16. ABSTRACT <p>This industry study is one of a series under the Office of Solid Waste Management Program of the Hazardous Waste Management Division, U.S. Environmental Protection Agency. The report concentrates on the rubber and plastics industry. It characterizes these industries in terms of number, location, size and age of plants, products, processes, etc.; identifies and quantifies those wastes which are or may be generated by these industries; describes current practices for treatment and disposal of potentially hazardous wastes; determines the control technologies which might be applied to reduce hazards presented by these wastes upon disposal; and estimates the cost of control technology implementations.</p> <p>The information presented in the report was acquired from a review of published information; trade association participation; personal contacts; visits to various plants and corporate offices of germane companies; waste sample analysis; and the application of an econometric model to project waste loads for 1977 and 1983.</p>

This report was prepared by Foster D. Snell, Inc., Florham Park,
New Jersey, under Contract No. 69-01-3194.

Publication does not signify that the contents necessarily reflect the
views and policies of the U.S. Environmental Protection Agency, nor
does mention of commercial products constitute endorsement by the
U.S. Government.

An environmental protection publication (SW-163c.2) in the solid waste
management series.

ACKNOWLEDGEMENTS

The preparation of this report was accomplished through the efforts of the staff of Foster D. Snell, Inc., a subsidiary of Booz-Allen & Hamilton Inc., Florham Park, New Jersey.

Mr. Matthew A. Straus, Staff Engineer, Hazardous Waste Management Division, was EPA Project Officer for the study. His assistance, leadership, careful review and advice made an invaluable contribution to the preparation of this final report.

Appreciation is extended to the following trade associations for assistance and cooperation in this program:

- . Rubber Manufacturers Association
- . International Institute of Synthetic Rubber Producers
- . Manufacturing Chemists Association
- . Textile Economics Bureau
- . Society of the Plastics Industry

Appreciation is also extended to the many rubber products manufacturers, plastic resin, synthetic rubber and fiber producing companies, who cannot be mentioned by name due to reasons of confidentiality, without whose assistance this report could not have been written.

Acknowledgement is also made of state and Federal agencies who gave invaluable assistance and cooperation in this program.

II. PLASTIC MATERIALS AND SYNTHETICS INDUSTRY -- SIC 282

This chapter characterizes and discusses the industry structure, the manufacturing processes, the total wastes generated and their treatment and disposal technologies and the associated costs for the potentially hazardous wastes identified for the Plastic Materials and Synthetics Industry, SIC 282.

The chapter's contents are presented as follows:

- . SECTION 1 -- INTRODUCTION AND GENERAL DESCRIPTION OF THE PLASTIC MATERIALS AND SYNTHETICS INDUSTRY
- . SECTION 2 -- CHARACTERIZATION OF THE PLASTIC MATERIALS AND SYNTHETICS INDUSTRY, SIC 282
- . SECTION 3 -- PROCESS DESCRIPTIONS, WASTE STREAM IDENTIFICATION AND WASTE CHARACTERIZATION AND QUANTIFICATION, SIC 282
- . SECTION 4 -- TREATMENT AND DISPOSAL TECHNOLOGY FOR POTENTIALLY HAZARDOUS WASTES GENERATED BY THE PLASTIC MATERIALS AND SYNTHETICS INDUSTRY, SIC 282
- . SECTION 5 -- COST ANALYSIS FOR THE TREATMENT AND DISPOSAL OF POTENTIALLY HAZARDOUS WASTES, SIC 282.

All tables and figures follow the text immediately after they are discussed.

1. INTRODUCTION AND GENERAL DESCRIPTION OF THE PLASTIC MATERIALS AND SYNTHETICS INDUSTRY

The following industry segments are included within SIC 282:

- . Plastic Materials and Resins SIC 2821
- . Synthetic Rubber SIC 2822
- . Cellulosic Man-Made Fibers SIC 2823
- . Organic Fibers, Non-Cellulosic SIC 2824.

Tables and figures discussed, follow in the section's text.

1.1 In 1972, SIC 282 Industries Employed Over 160 Workers And Produced Approximately \$10 Billion In Shipments

Table II-1 shows the number of employees, value added, value of shipments, and approximate number of establishments and companies for the plastic materials and synthetics industry in 1972. It also presents the relative importance of each of the SIC 282 segments in terms of employment and value added. The table is based on the 1972 Census of Manufacturers and indicates:

- . These industries have approximately 462 establishments with 70% within SIC 2821. Similarly, of the 289 companies reporting in SIC 282, 66% are classified in SIC 2821.
- . In terms of value added by manufacturers and value of industry shipments, SIC 2821 is also most important.
- . Only in terms of all employees is SIC 2824 the largest.

TABLE II-1

1972 STRUCTURE OF THE PLASTIC
MATERIALS AND SYNTHETICS INDUSTRY,
SIC 282

SIC Code (1)	All Employees (thousand) (% of SIC 282)	Value Added by Manufacture (\$ million) (% of SIC 282)	Value of Industry Shipments (\$ million) (% of SIC 282)	Approximate Number of Establishments (number) (% of SIC 282)	Companies (2) (number) (% of SIC 282)
2821	54.8 (33.8)	2,160.5 (43.8)	4,478.2 (45.7)	323 (70.0)	191 (66.0)
2822	11.8 (7.3)	491.7 (10.0)	1,089.4 (11.1)	59 (13.0)	50 (17.3)
2823	19.0 (11.7)	252.7 (5.1)	627.9 (6.4)	20 (4.0)	13 (4.5)
2824	76.3 (47.1)	2,031.1 (41.1)	3,601.4 (36.8)	60 (12.0)	35 (12.2)
282	161.9	4,936.0	9,796.9	462	289

Note:

- (1) SIC Codes by industry group and industry are:
 2821 Plastic Materials and Resins
 2822 Synthetic Rubber
 2823 Cellulosic Man-Made Fibers
 2824 Organic Fibers, Non-Cellulosic
 282 Plastic Materials and Synthetics

- (2) A company, as the term is used in the Census of Manufacturers, is a business organization consisting of one establishment or more under common ownership or control.

Source: U.S. Bureau of Census, Census of Manufacturers, 1972 Industry Series: Plastic Materials, Synthetic Rubber and Man-Made Fibers, MCT2(2)-282, U.S. Government Printing Office, Washington, D.C., 1974.

1.2 Many Of The Production Units In This Industry Are Part Of Large Plant Complexes

The Census Bureau classifies or segments industries in terms of establishments. This technique does not in many instances represent the proper method for reporting for the purposes of this study. This is due to the fact that establishments as reported in the Census may be manufacturing several classes of products both within and outside the scope of this study. This situation is the rule rather than the exception for the major plastic materials, synthetic rubbers and spinning establishments classified within SIC 282.

Foster D. Snell, Inc., therefore, identified the the number of production units within the establishments or plant complexes producing materials classified in each of the four industry segments of SIC 282. For the purposes of the study industry structure and waste quantification are reported in terms of production units so that a more realistic picture of SIC 282 could be provided.

A consequence of this approach is that a greater number of production units are reported in each four digit SIC by Snell than establishments as reported by the Census.

1.3 Polymerization And Spinning Are The Two Major Operations In SIC 282 Used For The Manufacture Of Their Products

Polymerization is the chemical reaction whereby repeating units of one or more molecular species are combined to form a large molecule. While this process can take several forms, e.g., solution, suspension, emulsion, etc., it is basic to the manufacture of all products in this industry.

Spinning operations are significantly different from the polymerization process in terms of equipment and type of physico-chemical changes occurring in the product formation. Fundamentally, this process is the extrusion of a polymer through a spinneret either in solution or as a melt to form a fiber.

1.4 There Are Eight Major Classes Of Ingredients Which Are Used In The Manufacture Of Polymers And Man-Made Fibers

The eight major classes of ingredients are presented in Table II-2 along with a discussion of their purpose in the manufacture of products in this industry.

These classes may be divided into two functional groups:

- The first group includes the monomers, catalysts or initiators and carrier fluids which are the basic feed requirements (raw materials) for polymer production.
- Modifiers, plasticizers, chemical additives, dyes and pigments and processing chemicals constitute the second group. These substances are used to alter the physico-chemical properties of the product so that they may be further processed.

The fact that there are two general groups of ingredients should not be construed as implying a two step operation in most cases. For instance, in SIC 2822 carbon black and plasticizers are added to the reaction mixture at the polymerization step, thus producing a "master batched rubber".

1.5 Products Produced By SIC 282 Are Critical In The U.S. Economy

This industry produces materials which are broadly dispersed throughout the U.S. economy and are used in the subsequent production of a variety of items.

TABLE II-2

**MAJOR CLASSES OF INGREDIENTS
USED IN THE MANUFACTURE OF
POLYMERS AND MAN-MADE FIBERS
SIC 282**

I.	<u>Monomers</u>	--	The building blocks of the resins or elastomers. Some monomers are treated by addition of small amounts of inhibitors to prevent autopolymerization in storage.
II.	<u>Catalysts and Initiators</u>	--	These chemicals are introduced to start the polymerization process and to accelerate the reaction.
III.	<u>Carrier Fluids</u>	--	These fluids may be water or organic solvents added to reduce the viscosity during polymerization and to improve the heat transfer.
IV.	<u>Modifiers</u>	--	Chemicals which are incorporated in the basic polymer chains so as to modify the physical properties (e.g., rigidity or tenacity) of the product.
V.	<u>Plasticizers</u>	--	Chemicals which are mixed with the polymers, but are not chemically incorporated. Their purpose is to make the polymer more pliable.
VI.	<u>Chemical Additives</u>	--	These are materials which are added to the polymer to modify the chemical properties of the product. For example, this may include antioxidants and photodesensitizers.
VII.	<u>Dyes and Pigments</u>	--	These may include organic as well as inorganic compounds. The dyes are dissolved in the polymer while the pigments are physically dispersed in the mass. Their purpose is to mask or impart color to the polymer.
VIII.	<u>Processing Chemicals</u>	--	These chemicals are used to control pH conditions or other physico-chemical parameters of the aqueous streams used in both the polymerization and spinning processes.

Source: Foster D. Snell, Inc.

For example, the following table demonstrates the pattern of consumption of one of the industry segments--Plastics and Resins (SIC 2821) for 1970. (Source: Modern Plastics, July 1973, and Foster D. Snell, Inc. estimates).

Table II-3 -- Consumption Of Products
Produced In SIC 2821

<u>Market</u>	<u>Present Consumption of Plastics in 1970</u>
Building and construction	24%
Packaging	27
Transportation	10
Electric/electronics	9
Furniture	4
Housewares	5
Appliances	3
Other	<u>18</u>
Total:	100%

In fact, the "other" category demonstrates the wide distribution. This category includes toys, textile and paper treating, agriculture, marine craft, signs, shoes and phonograph records.

Other SIC 282 products are similarly widely dispersed. Indeed the products of SIC 2824 constitute over 90% of all apparel worn in this country.

1.6 Wastes Generated By SIC 282 Establishments Are Generally Produced Directly As A Result Of The Unit Operations

Figure II-1, presents a generalized processing flow diagram. The following steps or unit operations are common to many processes within the industry:

- . Monomer(s) storage
- . Monomer preparation(1)
- . Monomer(s) feeding to the reactor
- . Carrier feeding to the reactor(2)
- . Catalyst feeding to the reactor
- . Reaction
- . Monomer(s) recovery
- . Carrier recovery(1)
- . Catalyst removal or recovery(1)
- . Polymer processing.

Waste streams generated by these unit operations include:

- . Inhibitor removal from monomer preparation
- . Still bottoms from monomer and carrier recovery
- . Catalyst wastes from catalyst removal or recovery
- . Off grade polymer or fiber product from production upsets which may occur at the reaction or polymer steps
- . Sludges from on-site wastewater treatment facilities.

In addition to these waste streams, others are generated by spillage in warehousing or storage areas, the action of particulate emission control equipment, lubricating oil changes and the discarding of defective packaging materials.

Notes: (1) Where required.

(2) Except for bulk processes.

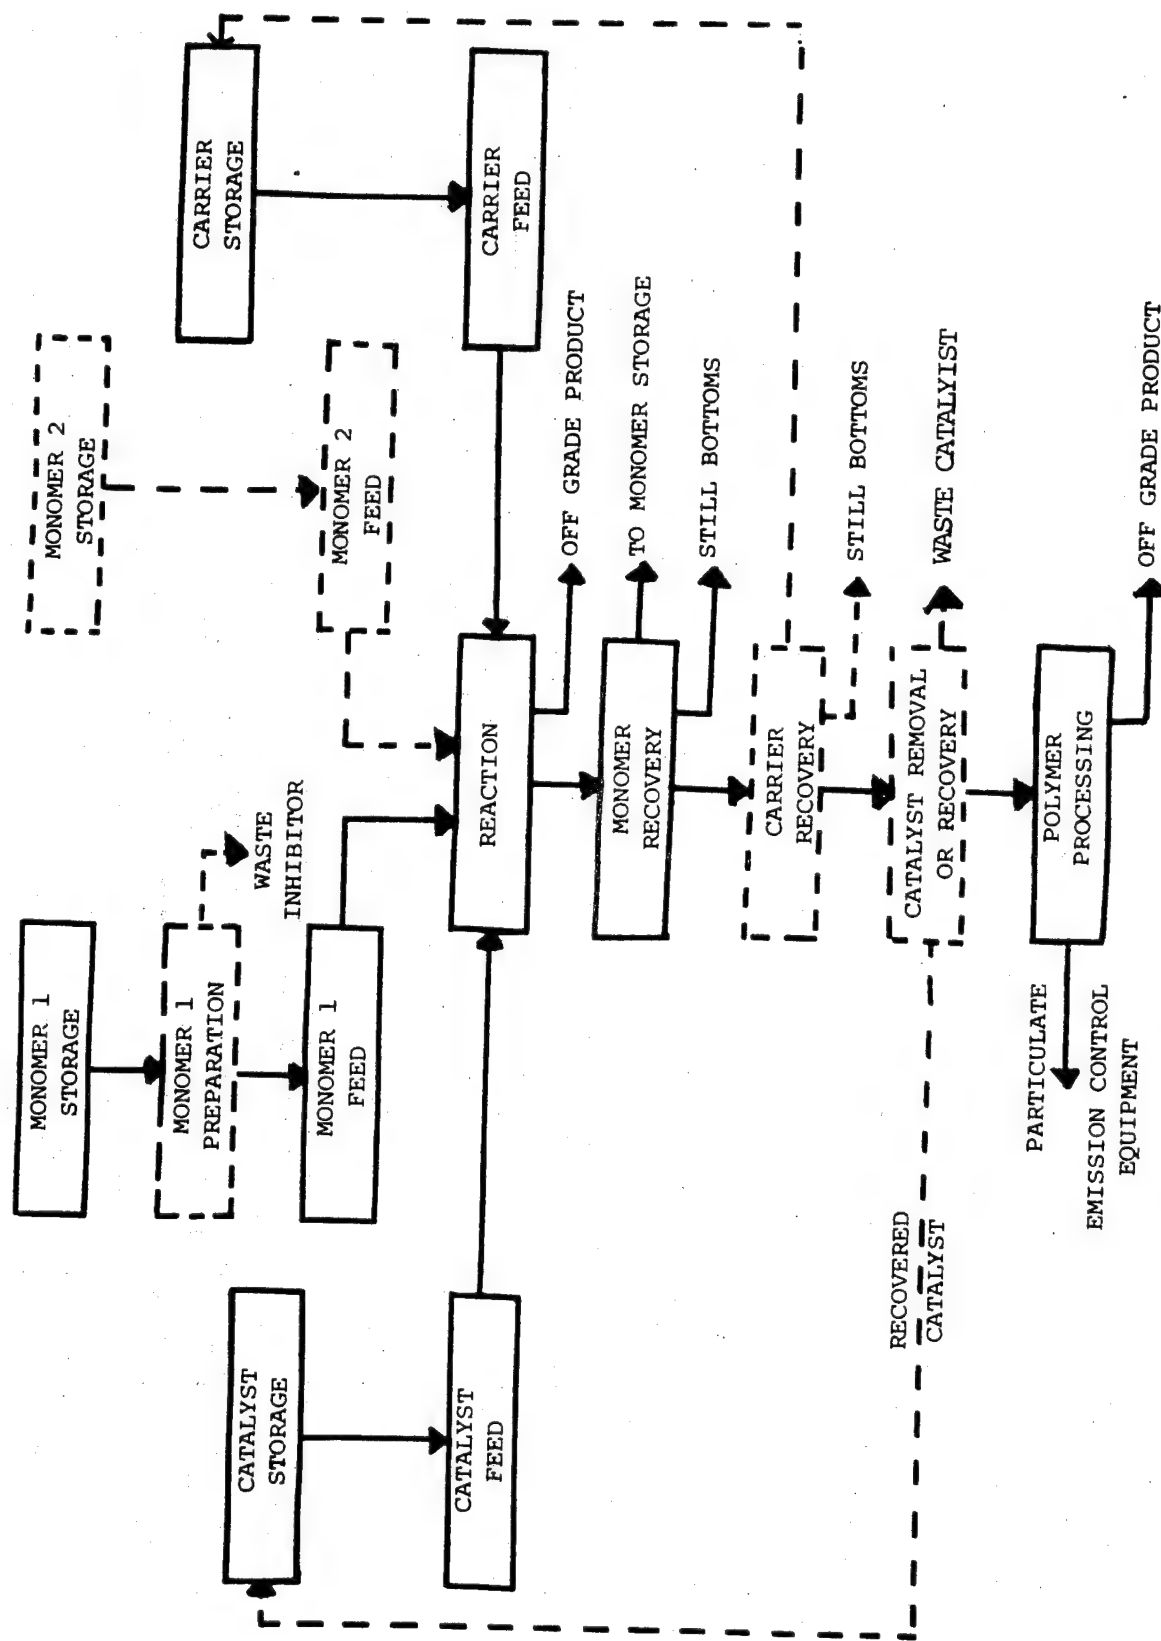

FIGURE II-1. GENERALIZED PROCESSING FLOW DIAGRAM

Note: Unit operations represented by dotted lines do not appear in all of the processes.
Differences between process types are discussed in the text.

Source: Foster, D. Snell, Inc.

1.7 A Significant Portion Of The Wastes Generated By
SIC 282 May Be Potentially Hazardous

Inhibitor wastes generated by monomer preparation, still bottoms from monomer and carrier recovery and off grade polymer may in certain cases contain organic materials which may be toxic or highly flammable.

Catalyst wastes from catalyst removal or recovery and sludges from on-site wastewater treatment facilities may contain metal ions such as tin, zinc, cadmium and nickel. These metals are considered to be toxic.

The potentially hazardous nature of these wastes varies with the product. Individual waste streams generated by the processes studied are characterized, on a case by case basis, in terms of their potential hazard in Section 4 of this chapter.

2. CHARACTERIZATION OF THE PLASTIC MATERIALS AND SYNTHETICS INDUSTRY

Tables D-1 through D-4 in Appendix D present a detailed definition of each of the four industry segments of SIC 282.

Table II-4 lists the principal products of SIC 282 in the order of decreasing importance in terms of estimated 1974 production volumes. The following conclusions may be drawn from the table:

- . The total 1974 estimate of production volumes for SIC 282 was on the order of 30,000 KKKg.
- . The greatest production in terms of weight was in SIC 2821 and 2824 with these industries accounting for approximately 85% of all production in SIC 282.
- . SICs 2822 and 2823 only accounted for approximately 15% of the production in the plastic materials and synthetics industry.
- . There are twenty-one important polymer types or classes produced by SIC 282 establishments. The first eight, polyesters, polyamides, polyethylene, vinyl resins, styrenes, polypropylene, acrylics and SBR account for over 85% of the total production by weight in SIC 282. In fact the first three account for over 50% of the production.

The remainder of this section details the industry structure by four digit SIC for each of the segments of the plastic materials and synthetics industry as follows:

- . Sub-Section 2.1 -- SIC 2821, Plastics Materials and Resins.
- . Sub-Section 2.2 -- SIC 2822, Synthetic Rubber.
- . Sub-Section 2.3 -- SIC 2823, Cellulosic Man-Made Fibers.
- . Sub-Section 2.4 -- SIC 2824, Organic Fibers, Non-Cellulosic.

TABLE II-4

ESTIMATED PRODUCT VOLUME OF
PRINCIPAL PRODUCTS OF THE
PLASTIC MATERIALS AND SYNTHETICS INDUSTRY,
SIC 282 (1974)

Product	Total Production	-----Production by SIC - KKKg/yr.-----			
		2821	2822	2823	2824
Polyesters	6,855 (1)	451			6,440
Polyamides	4,727	52			4,675
Polyethylene	4,018	4,018			
Vinyl Resins	2,277	2,277			
Styrene Resins	2,284	2,284			
Polypropylene	2,196 (1)	1,026			1,170
SBR	2,117	301	426		1,390
SBR	2,116		2,116		
Cellulosics	626	87		539	
Phenolics	610	610			
Polyurethanes	538	53	485		
Polybutadiene	477		477		
Amino Resins	377	377			
Alkyds	317	317			
Neoprene	177		177		
Butyl Rubber	166		166		
EPM-EPDM	166		166		
Coumarone-Indene	148	148			
Isoprene	142		142		
Epoxy	113	113			
Silicone	27		27		
	<u>30,474</u>	<u>12,078</u>	<u>4,182</u>	<u>539</u>	<u>13,675</u>

SBR = Styrene-Butadiene Rubber.

EPM-EPDM = Ethylene-Propylene Rubbers. EPM are copolymer and EPDM are terpolymers.

Note: (1) The quantity of production listed under SIC 2821 and SIC 2824 may not be additive due to possible transfers from 2821 to 2824.

Source: Foster D. Snell, Inc.

2.1 Structure Of The Plastics Materials And Resins Industry, SIC 2821

For this industry in 1972, value added by manufacturer was \$2,160.5 million according to the 1973 Census of Manufacturers, while value of shipments was \$4,478.2 million. There were over 54,000 employees working in SIC 2821 in 1972.

The products of this industry (i.e., polyethylene, polyvinyl chloride, etc.) are used throughout the U.S. economy with over 50% of production going into building and construction and packaging materials.

There are literally thousands of resin types produced by this industry. For the purposes of this study, the report focuses on those resins which are responsible for over 95% of the industrial production. These resins are:

- . High and low density polyethylene
- . Polyvinyl chloride
- . Polyvinyl acetate
- . ABS-SAN
- . Polystyrene
- . Polypropylene
- . Phenolics and other tar acid resins
- . Polyesters
- . Amino resins
- . Alkyds
- . Acrylics
- . Coumarone-Indene and petroleum resins
- . Polyurethanes
- . Cellulosic
- . Epoxy
- . Polyamides.

Appendix A presents the detailed methodology used in developing the data presented in the tables for this industry.

2.1.1 Geographic Distribution Of Plants And Their Capacities In SIC 2821

Table II-5 presents the geographic distribution of production units and their capacities for this industry segment.

Our survey has found that there are approximately 816 production units within SIC 2821. This value differs from the value of 323 establishments given in the 1972 Census of Manufacturers. It is felt that this discrepancy is due to the fact that while the study team is counting the number of sites where a particular resin is manufactured, the Census is, in reality, counting the number of plant complexes where several resins may be produced. For the purposes of the report, the study team's method of counting is more applicable because it provides a more realistic overview of the geographic distribution.

The highest concentration of production units and capacity is in the Atlantic states including New Jersey, New York and Pennsylvania, the Gulf Coast states such as Louisiana and Texas plus the states of Ohio, Michigan, Kentucky and California. In general, these are the locations of production sites for petroleum based chemicals required by the industry for its production processes.

Of the resins produced in SIC 2821, the greatest capacity exists for polyethylene manufacture with a total of 4,305 KKKg/yr., followed by polyvinyl chloride at 2,982 KKKg/yr. and polystyrene with a capacity for 1,935 KKKg/yr. Lower capacity exists for such products as epoxy resins at 136 KKKg/yr. and for polyamides at about 52 KKKg/yr.

2.1.2 Geographic Distribution Of Employment

Table II-6 presents the estimated 1974 geographic distribution of employment as a function of the number of production units. Information is presented as an aggregate for the entire SIC 2821 since employment figures related to each of the resins was not available.

- There was a total of 56,450 employees estimated to be working in the industry on an average of approximately 70 employees per production unit.
- Employment was concentrated in the same manner as production units and capacity discussed under 2.1.1.

The following data provides an estimate of production unit size distribution by employment on a national basis for SIC 2821 as a whole.

Table II-7 -- Production Unit Size Distribution By Employment, SIC 2821 (National Basis)

Number of Production Units	<div>10- 20- 50- 100- 250- 500- 1,000- 2,500</div>									
	1-4	5-9	19	49	99	249	499	999	2,499	or more
816	38	38	76	232	139	167	66	35	20	5

From the above information, it can be seen that the greatest number of production units (232) have between 20-49 employees and account for 28% of the industry. Most of the production units (66%) are in the size range between 20-249 employees. Only 3% of the production units have 1,000 employees or more. Nineteen percent have fewer than 20 employees.

Department of Commerce, Publication MC-72(2)-28B.

2.1.3 Distribution Of Plant Age

Distribution of plant age is not provided for SIC 2821 due to the inavailability of data. Most of the production units, however, were first constructed after the Second World War with many of the major ones being built in the late 1950's and early 1960's.

2.1.4 Geographic Distribution Of Production Volumes

Table II-8 is a summary of the geographic distribution of production volume by production unit for SIC 2821 as an aggregate for 1974.

Table II-9 presents the geographic distribution of the estimated production volume of the sixteen major SIC 2821 resins listed in Section 2.1.

From these tables, the following conclusions can be drawn:

- . Over 12,000 KKKg of resins were estimated to have been produced in 1974 by SIC 2821 production units.
- . The general concentration of production units and production was identical with that for capacities as shown in Table II-6.

For the entire SIC 2921 industry segment an average of approximately 15 KKKg of material was produced by each production unit in 1974. This value reflects the fact that there are many units producing only a small amount of resin. This is particularly valid for the phenolics, alkyd and polyurethane resins.

On the average, over 80% of the production capacity for SIC 2821 was utilized in 1974. For example, of the high volume resins:

- . Polyethylene was being produced at 93% of capacity
- . Polystyrene was at 95% of capacity
- . Polypropylene at about 84% of capacity
- . Polyvinyl chloride was being produced at 75% of capacity.

- (2) Production figures based on data from the 1974 Final Monthly Statistical Report, Plastic & Resin Materials, SPI Committee on Resin Statistics as compiled by Ernst & Ernst, March 21, 1975, and pro rated according to capacity.

II. 29

For typical lower volume resins, the following are estimates of capacity utilization for 1974:

- . ABS/SAN -- 78%
- . Polyesters -- 57%
- . Acrylics -- 65%
- . Epoxy -- 83%

2.2 Structure Of The Synthetic Rubber (Vulcanizable Elastomers) Industry, SIC 2822

For this industry in 1972, value added by manufacturers was \$491.7 million according to the 1972 Census of Manufacturers, while value of shipments was \$1,089.4. There were over 11,000 employees working in SIC 2822 in 1972.

The products of this industry are principally used in five segments of the U.S. economy: new tire production, tire retreading, molded rubber goods, footwear and adhesives. In 1973 about 65% of synthetic rubber production went into the production of new tires.

There are approximately 50 different types or classes of synthetic rubber or vulcanizable elastomers. Of these 50, nine are most important on a weight of production basis. These nine synthetic rubbers are, in decreasing order of importance, as follows:

- . Styrene-Butadiene Rubber (SBR)
- . Polyurethanes
- . Polybutadiene
- . Acrylics
- . Neoprene
- . Butyl rubber
- . Ethylene-propylene co- and ter- polymers (EPM and EPDM)
- . Isoprene
- . Silicone.

In general, this report focuses on the above nine elastomers since they represent over 95% of SIC 2822's production.

Appendix A presents the detailed methodology used in developing the data presented in the tables for this industry.

2.2.1 Geographic Distribution Of Plants And Production In SIC 2822

Table II-10 presents a summary of the geographic distribution of production units and their estimated 1974 production for this industry segment as an aggregate.

Table II-11 presents the geographic distribution of production units and their estimated 1974 production on a product by product basis.

- . Our survey has found that there are approximately 120 production units within SIC 2822.
- . The synthetic rubber industry is very heavily concentrated in the Gulf Coast area in such states as Texas and Louisiana, with a smaller grouping in Ohio and Kentucky and minor installations to Connecticut and Tennessee.

Of all the rubbers produced by SIC 2822, the greatest production in 1974 was of SBR type rubber and is estimated to be 2,116 KKKg. This value was on the order of almost four times the production for these next highest synthetic rubbers produced--acrylates, polyurethane and polybutadiene.

2.2.2 Geographic Distribution Of Employment

Table II-12 presents the estimated 1974 geographic distribution of employment. Information is presented as an aggregate for the entire SIC 2822 since employment figures related to each of the rubbers is not available.

- . There was a total of about 17,000 employees estimated to be working in the industry.
- . Employment was concentrated in the Gulf Coast (Texas and Louisiana) area with a smaller but sizeable grouping in the Ohio/Kentucky area.

The distribution of employment reflects the location of the plants near their suppliers of monomers (Gulf Coast) or their location near the major tire plants where about 65% of the production from SIC 2822 is used.

(1) Employment figures are estimated on the 1972 Census of Manufacturers and extrapolated in accordance with production information from this study.

Source: Rubber Red Book (1975), OPD Chemical Profiles, Ruebensaal's, The Rubber Industry Statistical Report.

The following data provides an estimate of production unit size distribution by employment on a national basis for SIC 2822 as a whole.

Table II-13 -- Production Unit Size Distribution
By Employment, SIC 2822 (National Basis)

Number of Production Units	Number of Employees							
	1-4	5-9	10-19	20-49	50-99	100-249	500-999	1,000-2,499
120	20	12	18	16	9	12	16	4

Source: Foster D. Snell, Inc.

From the above information, it can be seen that 63% of the production units have less than 100 employees. However, except for the four facilities with between 1,000 and 2,499 employees, the distribution is rather even in all categories.

2.2.3 Plant Age Distribution

Plant age distributions for the major synthetic rubbers (accounting for over 90% of SIC 2822 production in 1974) are presented on a product by product basis in a series of tables:

- . Table II-14 -- Styrene-Butadiene
- . Table II-15 -- Polybutadiene
- . Table II-16 -- Acrylonitrile-Butadiene
- . Table II-17 -- Neoprene
- . Table II-18 -- Butyl
- . Table II-19 -- Ethylene-Propylene
- . Table II-20 -- Isoprene

The bulk of the oldest and newest production units are those manufacturing styrene-butadiene rubber which was the type produced in the greatest quantity in 1974. Production units for all other rubber types are evenly distributed in regards to age.

Estimated plant age distribution for the plants presented in Tables II-14 through II-20 are summarized in Table II-21.

estimates.

- . Eighteen of the production units are in the range of 0-9 years old.
- . Twenty-three are between 10-19 years old.
- . Only four are 20-29 years old.
- . Twenty are over 30 years old.

2.3 Structure Of The Man-Made Fiber Industry, SICs 2823 And 2824

This sub-section discusses the industry structure for both fiber producing segments of the plastics materials and synthetics industry.

- . SIC 2823, Cellulosic Man-Made Fibers
- . SIC 2824, Man-Made Fibers, Non-Cellulosic.

For the man-made fiber industry, the value added by manufacture was \$2,283.8 million according to the 1972 Census of Manufacturers, while the value of shipments was \$4,229.3 million. There were over 95 thousand employees working in this industry in 1972. The split between SICs 2823 and 2824 for these values were as follows:

- . For SIC 2823, the value added by manufacture was \$252.7 million, value of shipments was \$627.9 million and employment was 19,000 total workers.
- . For SIC 2824, the value added by manufacture was \$2,031.1 million, the value of shipments was \$3,601.4 million and employment totalled 76,300 workers.

From these figures, it is apparent that the cellulosic fiber industry is significantly smaller than the non-cellulosic segment of SIC 282. In fact, SIC 2823 is the smallest segment of SIC 282 in terms of employment, value added by manufacture, value of shipments, number of establishments and production volume on a weight basis. The non-cellulosic fiber industry, SIC 2824 is exceeded in the above terms within SIC 282 only by the plastic materials and resins group, SIC 2821.

The products of the fiber industry find use throughout the U.S. economy. For example, major end-uses of cellulosic and non-cellulosic fibers are listed below in order of product mix importance. (1)

- . Broad woven goods: 43%
- . Flat knit goods: 15%
- . Non-woven goods: 12%
- . Tires: 6%

All of these end-uses are important in the economy.

There are two important cellulosic fiber classes produced by SIC 2823:

- . Rayon
- . Acetates and triacetates

and four important non-cellulosic fiber classes produced by SIC 2824:

- . Polyesters
- . Nylon and aramids
- . Acrylics and modacrylics
- . Polyolefins and vinyon.

In general, this report focuses on the above listed cellulosic and non-cellulosic fibers. These materials represent over 95% of production in SICs 2823 and 2824.

(1) Foster D. Snell, Inc., Industrial Energy Study Of The Plastics And Rubber Industries, SICs 282 and 30. Contract Number: 14-01-0001-1655, U.S. Department of Interior, Bureau of Mines, Washington, D.C. (1974).

2.3.1 Geographic Distribution Of Production Units And Employment, Man-Made Fiber Industries, SICs 2823 And 2824

Table II-22 presents the estimated 1974 geographic distribution of production units and employment for the man-made fiber industries.

- Our survey has found that there are approximately 166 production units within these industries.
- The cellulosic and non-cellulosic fiber industries are both concentrated in the South Atlantic states near the large textile mills. These states of high concentration include Tennessee, North Carolina, South Carolina and Virginia.

Employment values are given as an aggregate for both SICs comprising the fiber industry. This approach was taken because in many cases there are several production units at one site and in some instances these units are in both SICs 2823 and 2824.

2.3.2 Plant Age Distribution

Estimated plant age distributions for the fiber groups of SIC 282 were developed with the assistance of the Textile Economics Bureau.

2.3.2.1 Cellulosic Man-Made Fiber Industry, SIC 2823

Table II-23 presents the estimated production unit age distribution for this industry. The majority of production units (10 out of 13 still in production) are over 30 years of age. One production unit is in the range of 10 to 20 years old and the remaining two began production 20 to 30 years ago.

TABLE II-22

		X				1			(D)	

(1) Employment is total for both SIC 2823 and 2824 as in many cases there are several production units at one site and in some instances these units are in both SICs.

(2) (D) = data not presented to avoid disclosure.

Key:

A - Aramid	P - Polycarbonate	SIC 2823 = Cellulosic Manmade
B - Biconstituent	S - Saran	Fiber Industry
F - Fluorocarbon	V - Vinyon	SIC 2824 = Non-Cellulosic Manmade
M - Modacrylic	X - Spandex	Fiber Industry

2.3.2.2 Non-Cellulosic Man-Made Fiber Industry, SIC 2824

Estimated production unit age distribution for this industry are presented in Table II-24.

As can be seen from a comparison of Tables II-23 and II-24, SIC 2824 is a newer industry than SIC 2823. A summary of production unit ages is provided below.

Table II-25 -- Summary Of Ages Of Production Units, SIC 2824

<u>Total Number of Production Units Identified</u>	<u>Production Unit Age (Years)</u>				
	<u>4 or Less</u>	<u>5-9</u>	<u>10-19</u>	<u>20-29</u>	<u>30 or More</u>
153	52	46	40	11	4

Source: Foster D. Snell, Inc.

Over 66% of the production units are between less than 5 years old to 10 years in age. Only approximately 3% are thirty years old or more.

The oldest units are generally those producing nylon and spandex. The newest production units are those manufacturing polyolefins, polyesters and some small volume fibers such as fluorocarbons and polycarbonates.

Table II-26 through II-30 present production unit ages of the individual fibers in SIC 2824.

2.3.3 Geographic Distribution Of 1974 Capacities And Production

Much of the information concerning capacities and production for the cellulosic and non-cellulosic fiber industries cannot be presented on a state basis in order to prevent disclosure of proprietary information.

2.3.3.1 Cellulosic Man-Made Fiber Industry,
SIC 2823

Table II-31 presents the estimated geographic distribution of cellulosic fiber capacities for 1974. Table II-32 does the same for production.

- Total reported capacity was 3,435 KKKg in 1974. Capacity was split almost equally between the rayon and acetate classes of fibers.
- Total reported cellulosic fiber production was approximately 537.6 KKKg in 1974. This was only 15% of the reported capacity.

Most production in this industry centered in the South Atlantic states.

2.3.3.2 Non-Cellulosic Man-Made Fiber
Industry, SIC 2824

Table II-33 presents the estimate geographic distribution of non-cellulosic man-made fiber capacities for 1974. Table II-34 does the same for production.

- Total reported capacity for 1974 was 17,592 KKKg. The greatest capacity exists for polyester based fibers followed by the nylons. These two fibers account for approximately 81% of U.S. capacity for fiber production.
- Total reported production was 137,000 KKKg in 1974. This represented an over 77% capacity utilization which was over five times that for cellulosic fibers.

As in the case of cellulosic fibers, non-cellulosic production is centered in the South Atlantic states near the large textile mills.

3. PROCESS DESCRIPTIONS AND WASTE STREAM IDENTIFICATION FOR
THE PLASTIC MATERIALS AND SYNTHETICS INDUSTRY, SIC 282

There are two major groups of processes used in SIC 282: polymerization and spinning. Because polymerization processes are similar for all segments of this industry, the SIC Classification framework for the discussion presented below is not maintained. Instead, these topics are presented in a manner more descriptive of the actual conditions in the industry.

The section is organized as follows:

- . General description of the polymerization process to provide a technical framework for the understanding of the individual processes.
- . General description and quantification of waste stream factors.
- . Specific, more detailed description of the processes and waste streams. This description is subdivided into several parts so that the various aspects of SIC 282 are covered in a logical format. In particular, regarding plastic resins and synthetic rubber, the discussion addresses itself to:
 - Processes and waste streams associated with olefinic polymers
 - Processes and waste streams associated with the non-olefinic polymers used in man-made non-cellulosic fiber manufacture
 - Process and waste streams associated with the principal other non-olefinic polymers
 - Processes and waste streams associated with the production of man-made cellulosic polymers
 - Processes and waste stream associated with the spinning operations.

Note that for the purposes of this study the term olefinic polymer refers to those polymers where the main linkage generally occurs at a carbon-carbon double bond site.

3.1 Introduction

This section provides a general description of the polymerization process and of the waste streams generated.

The rationale for this approach is that there exist fundamental similarities among most of the polymerization processes. However, this section does not discuss the processes involved in the production of cellulosic man-made polymers nor the various spinning processes which are discussed separately in the last paragraphs of the following section. This is because:

- Cellulosic man-made polymers are prepared by different methods from the production of the other synthetic polymers (albeit often at the same production sites).
- Spinning operations are a different technology from polymerization.

3.1.1 General Description of the Polymerization Process

In general, polymerization is the linking together of single molecules (monomer) to form repeating units of one or several molecular species. Two problems of the polymerization process are:

- The efficient removal of the considerable amount of heat generated in the process of polymerization.
- The change of phase to an extremely viscous or even solid material of a liquid or gaseous monomer.

These two problems are usually solved simultaneously by providing a carrier fluid for the final product. In most instances, this carrier fluid is water; in which case the processes are described as emulsion or suspension polymerization. When the carrier fluid is not water, it can be an organic solvent. In this case, the process is known as solution polymerization. Another approach is that of using an excess monomer acting as a solvent. These processes are known as bulk polymerization.

The above processes can be run batchwise, semi-continuously or continuously.

Pressures involved in the reactions may vary from near atmospheric to thousands of atmospheres (40,000 p.s.i.). Temperatures may range from near room temperature, 20°C (70°F) to 175°C (300°F). Catalysts or initiators may be involved. However, in most cases they are consumed in the process or are incorporated in the final product. Spent catalysts may sometimes become part of the waste stream.

The following steps that are common to most processes have been previously listed on p. II-8 and include:

- . Monomer(s) storage
- . Monomer(s) feeding to the reactor
- . Carrier feeding to the reactor (except for bulk processes)
- . Catalyst feeding to the reactor
- . Reaction
- . Monomer(s) recovery
- . When required, carrier recovery
- . Processing of the polymer.

These steps and their interactions are presented in Figure II-1.

In some instances it is necessary to condition the monomer by removing the inhibitor.

Most facilities produce hundreds of millions of pounds per year. However, about 10% of the total production is carried out in extremely small scale operations, i.e., several thousand pounds per year.

Tables II-35 and II-36 summarize the production elements for the major plastics and synthetic rubbers, respectively.

3.1.2 General Description Of The Waste Streams From Polymerization

The waste streams produced in polymerization are described next. There are six major classes of waste streams.

Table II-35
SUMMARY OF PRODUCTION ELEMENTS IN THE
PLASTIC RESINS INDUSTRY --
SIC 2821

Product	Process	Carrier Fluid	Monomer(s)	Initiator or Catalyst (1)	Additives
Polyethylene Low Density High Density	Modified Bulk Solvent	Solvent (80-90°C B. P.)	Ethylene (2) Ethylene (2)	Organic peroxides Ziegler/Phillips (3)	
Polyvinyl Chloride	Suspension/Emulsion Bulk	Water None	VCM VCM	Lauroyl peroxide azobisisobutyronitrile (same)	Polyvinyl alcohol, gelatin, methylcellulose Proprietary (if any)
Polystyrene	Suspension Bulk/Solution	Water Ethylbenzene	Styrene Styrene	Lauroyl peroxide azobisisobutyronitrile Benzoyl peroxide Butyl perbenzoate	Tetracalcium phosphate, surfactants, dyes
ABS-SAN	Emulsion	Water	Acrylonitrile, butadiene, styrene	Peroxides	Carbon tetrachloride, shortstop (hydro- quinone) pigments, plasticizers
Polypropylene	Solution	Heptane, cyclohexane xylene	Propylene	Ziegler (Al, Ti)	Antioxidants, fillers, plasticizers, antistats
Phenolics	Emulsion	Water (4)	Formaldehyde (37% phenol and substituted phenols	Alkalies or Acids	Solvents, oils, plasticizers, wood flour, other resins, e.g. amino resins
Polyesters (5)	Mass	None	Polyalcohols, dibasic acid or anhydride	Acetates of cobalt, manganese or cadmium	Styrene, hydroquinone
Alkyds	Fusion (mass) Solvent (solution)	None Xylene, mineral spirits	Phthalic anhydride Fatty acids, oils, glycols, polybasic acids	None	
Acrylics	Emulsion/Suspension Solvent Bulk	Water Various solvents Monomer	Acrylates Acrylates Methyl methacrylate	Emulsifiers, persulfates Peroxides	Reducing agents, ferroc ammonium sulfate
Polyamides Nylon 6,6	Suspension	Water	Hexamethylene diamine	None	Acetic acid, TiO ₂ spin finishes
Nylon 6	Suspension	Water	Caprolactam	Nylon 6,6 or 6 amino caproic acid	Acetic acid, TiO ₂ spin finishes

ABS-SAN = Acrylonitrile butadiene styrene-Styrene acrylonitrile

- (1) The terms catalyst and initiator are used somewhat interchangeably, in polymerization. Initiators are, by definition, used up in the reaction and their decomposition products are usually discharged with the polymer. Catalysts are seldom separated at the end of the reaction.
- (2) Copolymerization is frequent (a current comonomer may be vinyl acetate).
- (3) Ziegler catalysts = isopropyl or isobutyl hydrides -- Phillips. A ceramic type chromium oxide, aluminum oxide finely divided solid.
- (4) The water is supplied from the use of a water solution of formaldehyde (Formalin 37%).
- (5) The bulk of the production is for fiber and is often carried out in fiber plants. (SIC 2824).

3.1.2.1 Off-Grade Products

The main waste stream, in these processes, consists of off-grade products. The reasons are production upsets, product changes, mechanical failures and abrasion in handling.

3.1.2.2 Still Bottoms

This stream originates in monomer or solvent recovery. It is composed of high boiling residues called still bottoms, which are separated in the distillation process. These residues consist of relatively low molecular weight, shortchain polymerized material and other organic products resulting from chemical degradation of product or solvent.

3.1.2.3 Spent Adsorbents And Filters

Granular or pulverulent material (adsorbent) is used to condition the monomer by removing traces of water. This material is eventually discarded, and, together with the filter elements used from its separation from the production stream, constitutes a significant solid waste stream.

3.1.2.4 Spent Catalysts

In some processes, spent catalyst constitutes a separate waste stream. In this industry, in many cases, the catalyst is allowed to remain in the finished product and thus does not constitute a waste stream. In other cases, the catalyst goes to the wastewater treatment facility and becomes part of the sludge.

3.1.2.5 Waste Oils

There are two sources of waste oils:

- Spillage from gear boxes and bearings of rotating equipment
- Oil changes.

The spillage usually finds its way to run-off sewers or floor drains. If spillage at a plant is significant, traps are provided to collect the waste oil. Spent lubricating oils are generally collected in drums.

3.1.2.6 Wastewater Treatment Sludges

The plants in which most of the polymerization processes are carried out have usually some form of treatment facilities for their wastewaters. The contribution of the polymerization processes does not constitute, in the majority of cases, the bulk or even a major portion of the wastewater loads. This is due to the fact that at most plant locations other processes are carried out which require large quantities of process water, and which are more likely to contaminate the water with undesirable components.

The treatment of wastewater generated in chemical plants usually involve at least a clarification step.

Clarification may be preceded by such steps as pH adjustment and/or the addition of flocculant or coagulant. Clarification produces a sludge which may contain solids from the polymerization process. In addition to the catalysts discussed in the previous paragraph, the primary sludges may also contain fines from the polymerization processes.

In addition, there may be a secondary treatment operation in which soluble contaminants (e.g., alcohols) from the polymerization are oxidized biologically and produce a biological sludge.

Because SIC 282 plants are usually part of large chemical complexes, the contribution of the polymerization processes to the total wastewater load is minor.

3.2 Detailed Process Descriptions

In this section, the various processes used to manufacture the subject polymers are discussed in more detail. Although many classifications and segmentations are valid, the general framework for the discussion is based on a segregation of the processes into five groups. The first four groups cover the processes used in the manufacture of the polymers, while the last group addresses itself to the spinning.

In view of processing commonalities, the first group of processes discussed contains those used for what we call the olefinic polymers. This group encompasses most of the major polymers derived from olefinic materials, with the addition of vinyl chloride and acrylonitrile. The group encompasses all the major synthetic elastomers and the other major resins (i.e., polypropylene, polyethylene, styrene butadiene rubber).

A second group consists of the three classes of polymers used in the non-cellulosic fiber industry. These are less directly related to the petrochemical industry because the monomers involved are produced in chemical plants (i.e., acrylics, polyesters).

A third group consists of other non-olefinic resins, usually manufactured by batch processes. In terms of volume of production, this group is dominated by the phenolics and amino resins (i.e., phenolics, epoxies, alkyd resins).

The fourth group comprises the cellulosic man-made (or man-modified) polymers (i.e., rayons and acetates).

3.2.1 Processes And Waste Streams Associated With The Production Of Olefinic Polymers

The types of polymers included in this group are as follows:

- . Styrene Butadiene Rubber (SBR)
- . Polyethylene: low and high density
- . Polyvinyl Chloride and Polyvinyl Acetate
- . Polystyrene and other styrene resins (ABS* and SAN**)
- . Polybutadiene
- . Polypropylene
- . Neoprene
- . EPM-EPDM Rubbers
- . Polybutenes and Copolymers.

Table II-37 illustrates the waste factors associated with the above olefinic polymers.

The processes used include:

- . Emulsion and suspension polymerization
- . Mass or bulk polymerization
- . Solution polymerization.

* ABS= Acrylonitrile butadiene styrene
** SAN= Styrene acrylonitrile

A series of figures are provided to illustrate the processes and waste streams discussed under olefinic polymer.

- Figure II-2 -- Emulsion/Suspension Polymerization
- Figure II-3 -- Bulk or Mass Polymerization
- Figure II-4 -- Solution Polymerization, Phillips Process
- Figure II-5 -- Solution Polymerization, Ziegler Process
- Figure II-6 -- Particle Form Polymerization

3.2.1.1 Emulsion And Suspension Polymerization

Figure II-2 presents a flow diagram of a typical emulsion/suspension polymerization process. The wastes include:

- . Off-grade products--fines and scrap pellets
- . Still bottoms--polymer waste
- . Wastewater sludges.

A large number of polymers are manufactured by processes in which the monomer is dispersed in an aqueous, continuous phase during the course of the reaction. There are technical differences between emulsion and suspension systems which pertain to the polymerization reaction itself, but do not have a bearing on the waste production. Therefore, both methods are covered by this discussion.

Batch processes are commonly used. Typical reactor size is 18.9 to 113.5 m³ (5,000 to 30,000 gal.). The batch cycle consists of the continuous introduction of a water-monomer emulsion with agitation. Polymerization occurs at about the rate of monomer addition; the heat of reaction is removed by cooling tower water circulated through the jacket. The reactor is vented through a condenser for monomer recovery; and the condensate, including any water, is returned directly to the vessel. On completion of the batch, a short "soaking" time is allowed for completion of the reaction, and water is then added to dilute to the desired end composition. The batch is drawn off through a screen to product storage. Over-size screenings constitute a waste stream.

A number of products, polyvinyl acetate for example, are marketed in latex form with no further processing required. When the product is isolated and sold in solid form, the screen latex is pumped to another tank where it is coagulated. The liquid phase is separated by centrifugation or filtration and the cake is dried.

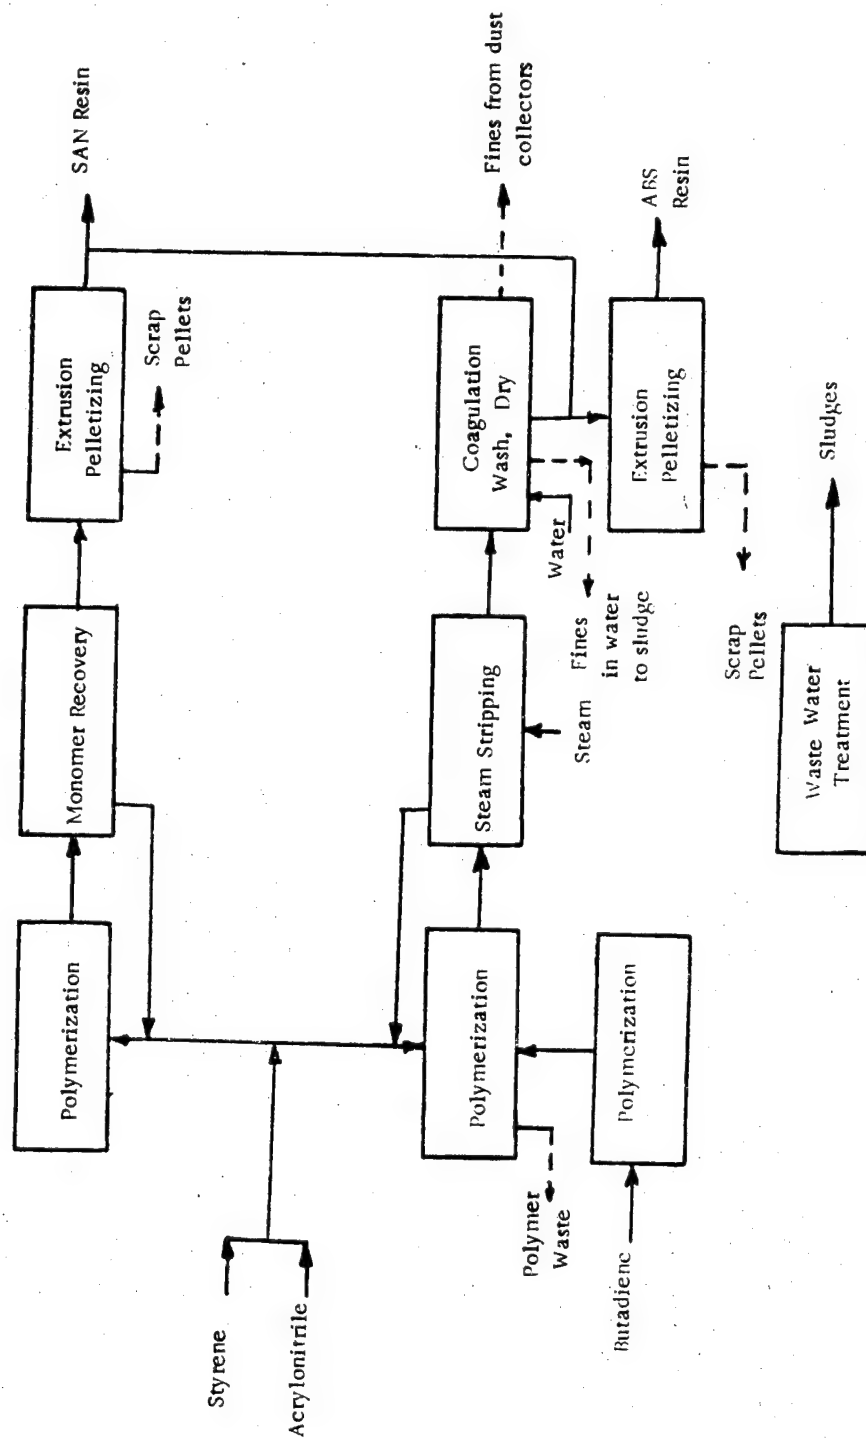

FIGURE II-2
EMULSION/SUSPENSION POLYMERIZATION FLOW DIAGRAM

Source: Environmental Protection Agency Study (Contract No. 68-01-0030)

The emulsion process is probably the most important in polymer manufacture. It is used in particular in the production of the following olefinic polymers:

- . Styrene-butadiene rubber (SBR)*
- . Polystyrene
- . Acrylonitrile butadiene styrene (ABS)
- . Styrene acrylonitrile (SAN)
- . Polyvinyl chloride (PVC)*
- . Polyvinyl acetate (PVAC)
- . Neoprene.

3.2.1.2 Mass Or Bulk Polymerization

In these processes, an excess of the monomer is used as the diluent or carrier fluid. There are two types of processes:

- . Low pressure polymerization
- . High pressure polymerization.

Figure II-3 presents a typical bulk or mass polymerization flow diagram.

3.2.1.2.1 Atmospheric Or Low Pressure Mass Polymerization

A number of important polymers are manufactured by mass polymerization, a system in which the purified monomer is allowed to polymerize under controlled conditions of temperature and reaction rate. Catalysts and modifiers are used to initiate the reaction, control its rate, and influence the final molecular weight. These materials are used in very small quantities, and their residue remains in the product. Removal of the heat of reaction is a difficult problem in this process and limits the type of equipment which can be used.

* A substantial production of these polymers is carried out also by other processes, e.g., solution or mass (or bulk) polymerization.

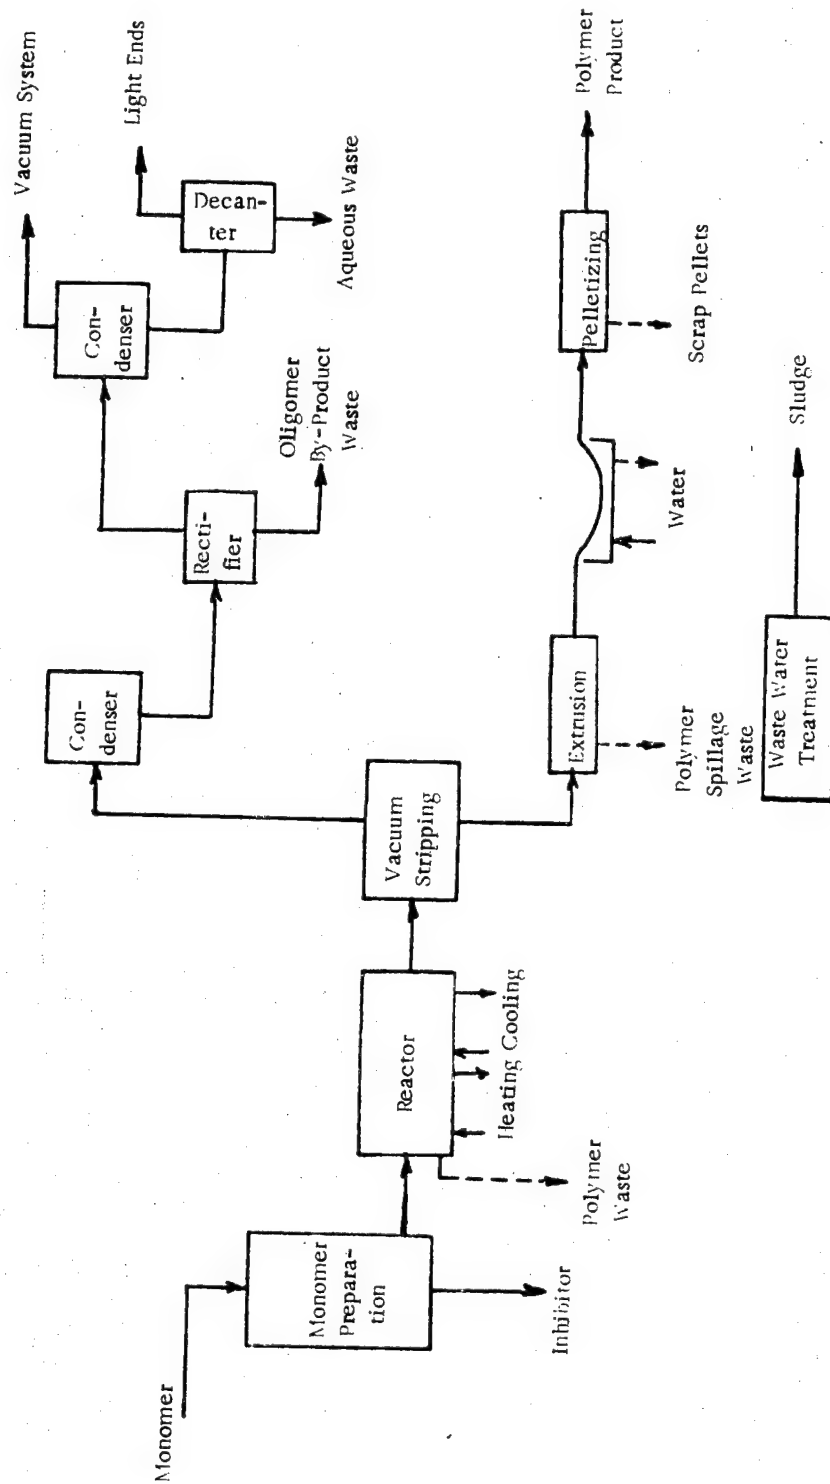

FIGURE II-3
EPA
BULK OR MASS POLYMERIZATION FLOW DIAGRAM

Source: Environmental Protection Agency Publication EPA-440/1-74-010-a

It is usually necessary to protect the purified monomers from autopolymerization in storage. The inhibitor used for this purpose is removed by monomer preparation. The reaction system is usually continuous, or multi-stage, and the first step is to bring the monomer to reaction temperature by indirect heating. A heat-transfer oil or fluid, such as Dowtherm, circulated from a fired heater, is used. Once reaction begins, the heat is removed by transfer to cooling oil circulated through coils or in a jacket. The circulated oil is cooled by water in conventional heat-exchange equipment.

On leaving the reactor, the polymer contains unreacted monomer and small amounts of contaminants and by-products. These materials are removed by vacuum stripping. The recovered monomer is then treated in a rectifier. The contaminants and by-products constitute the oligomer by-product waste (still bottoms). Pure polymer is forced through extrusion to make strands of polymer, which are cooled in a water bath before pelletizing for storage and shipment.

Other wastes include off-grade product, polymer waste and scrap pellets.

Products of this process include:

- . Polystyrene (PS)
- . Acrylonitrile, butadiene, styrene (ABS)
- . Styrene, acrylonitrile (SAN)
- . Polyvinyl chloride (PVC).

3.2.1.2.2 High Pressure Mass Polymerization

This process is mainly used for the manufacture of low density polyethylene.

Ethylene gas is mixed with a very small quantity of air or oxygenated organic compounds as a catalyst and with recycled ethylene, and raised to high pressure in reciprocating compressors.

The operating pressure is considered to be confidential information, but the trend in the industry has been to the highest practical pressures, and literature references to design ratings of 40,000 psi (2,722 atm) and up are common. At the operating pressure and at an appropriate temperature, polymerization is carried out in jacketed tubular reactors. The heat of reaction is removed to hot water in the jacket, which circulates through a waste heat boiler for the generation of steam.

On completion of the reaction, the pressure is reduced and polymer meeting the specified properties is separated in flash drums. This molten material is pumped through a multiple orifice extruder to an underwater chiller and chopper to produce polyethylene pellets. A purge stream of this water is removed and replaced with high-quality, clean water. The purge is at a rate sufficient to remove polymer fines generated in chipping. The quantity of fines depends on the grade of polymer produced and with some grades is negligible. Wet polymer from the screen is dried and stored in silos.

The waste factors in the production of low density polyethylene consist mainly of off-grade products (1% of total production) and still bottoms and waste oils (1% of total production).

3.2.1.3 Solution Polymerization

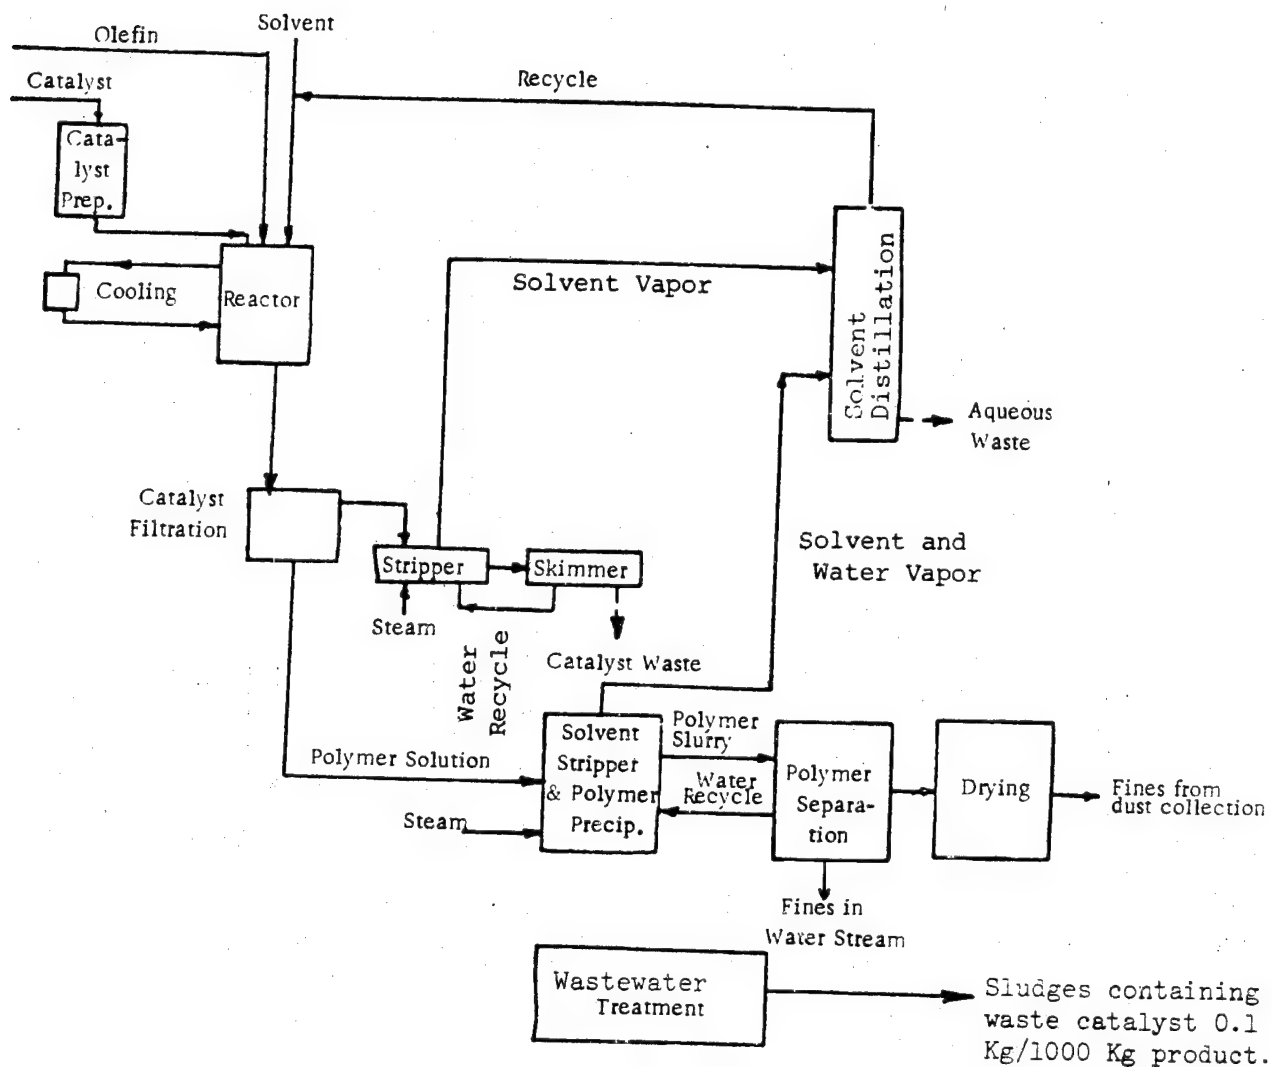

There are two main variants of this process, basically depending on the type of catalyst used. The Phillips processes use a chromium oxide or alumina type of catalyst and the Ziegler processes use metal alkyl catalyst. A recent variant of these processes is called the particle form process.

3.2.1.3.1 Solution Polymerization (Phillips Processes)

In this process (Figure II-4), the polymer is dissolved in the reaction solvent as it is formed, and the catalyst is present as a separate solid phase. The catalyst system is activated chromium oxide deposited on a carrier, such as alumina.

FIGURE II-4

SOLUTION POLYMERIZATION
(PHILLIPS PROCESS)

Source: EPA publication EPA-440/1-74-010-a

As the concentration of polymer, or the molecular weight of the polymer in solution increases, the viscosity of the solution also increases markedly. This phenomenon places severe limitations on the processability of the reaction mass. Temperature control is accomplished by indirect cooling with refrigerated water, and the viscosity must not be allowed to exceed a reasonable limit for efficient heat transfer.

Viscosity is also an important limitation in the next step, which is the removal of the catalyst by filtration. From the filter, the catalyst, wet with solvent, is mixed with hot water and the solvent removed by steam stripping. Solvent-free catalyst slurry is processed in a skimmer and solid catalyst is produced as a waste.

The water is recycled to the steam solvent stripper. Vapor from the steam stripper is combined with other recovered solvent for purification by solvent distillation.

The catalyst-free polymer solution is processed in a system which precipitates the polymer, and then removes the last traces of solvent by steam stripping, leaving the polymer as a slurry in water. The polymer water slurry goes to polymerization, and the filtrate is recycled to the stripper.

Recovered solvent and vapors from the steam strippers are processed by the solvent distillation system.

Dry polymer crumb or flake is blended, melted, extruded and pelletized. This pelletizing operation is carried out under water, with cooling and transport accomplished with recirculated, clean, softened water. A purge stream amounting to a few percent of the circulation rate is withdrawn to waste. This system is the same as that already described for the low density polyethylene process.

The principal product of this process is high density polyethylene. However, the process is also used for some copolymers in this family of products.

3.2.1.3.2

Solution Polymerization (Ziegler Processes)

This process (Figure II-5) depends on a catalyst system discovered and patented by Dr. Karl Ziegler. There have been a number of improvements by companies using the basic principle, and the name in fact applies to the catalyst system. Each user has had to design his own plant. However, it is convenient to group under this name all polyolefin processes which employ a reaction solvent in which the polymer precipitates as it is formed. The catalyst is a relatively complex alkyl, or alkyl halide, of metals such as titanium and aluminum.

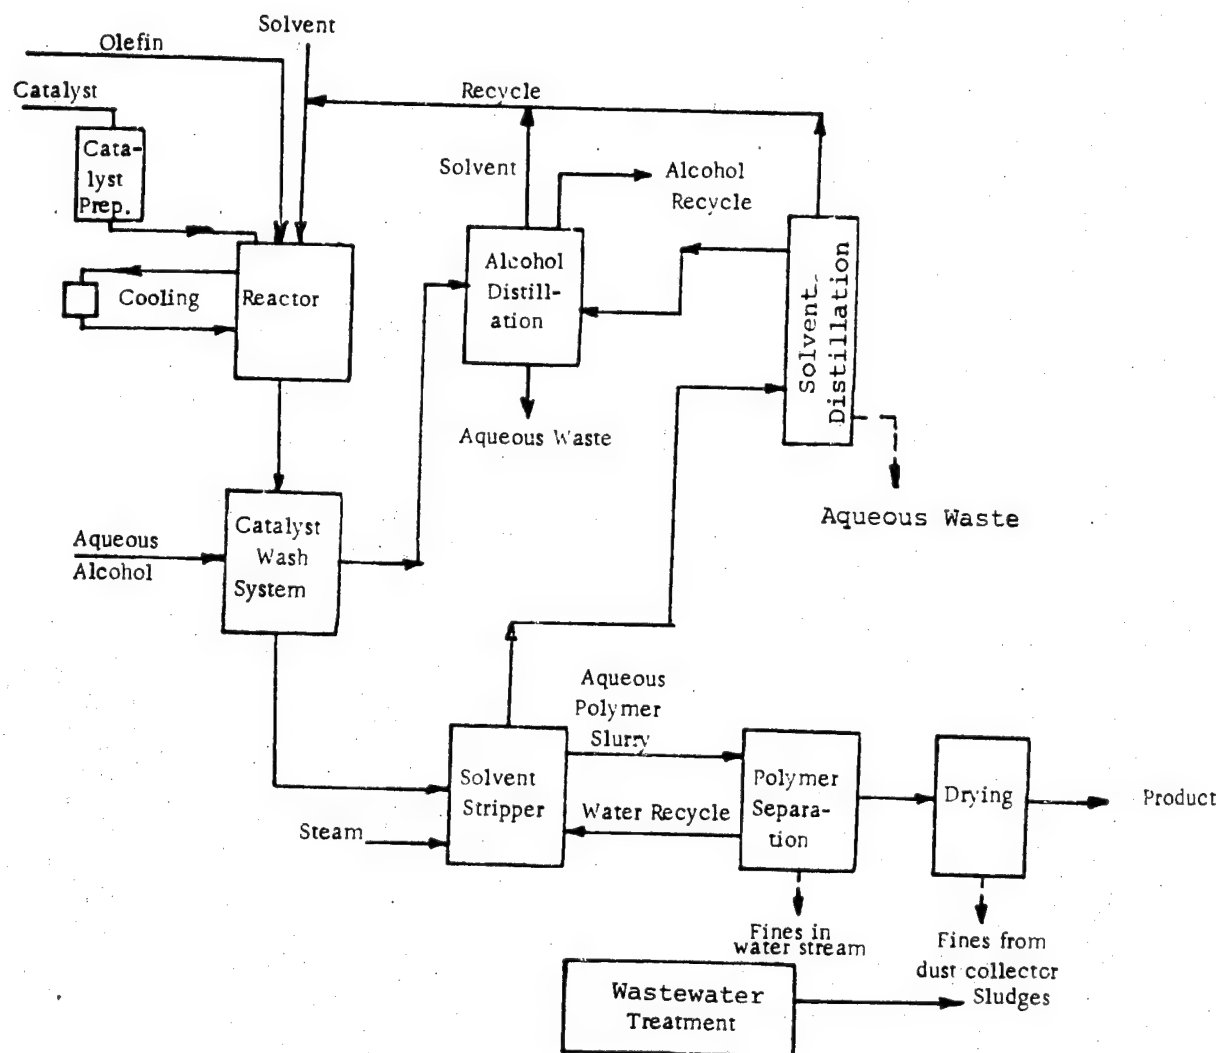

Catalyst preparation, monomer addition, and reaction proceed as for the solution process described in 3.2.1.3.1. Temperatures and pressures are lower; and, because the polymer does not dissolve, problems caused by excessive viscosity do not arise.

The next step is the removal of the catalyst, which historically has been the most troublesome part of the system. The residual catalyst content of the final polymer must be very low, and for this reason a system is employed which allows transfer of catalyst to a separate liquid phase. Aqueous alcohol is used for this purpose and the catalyst is removed in solution, leaving the polymer slurried in the hydrocarbon solvent.

The aqueous alcohol phase is treated to precipitate the catalyst as the oxides (e.g., titanium, aluminum), and these materials eventually appear as finely-divided suspended solids in the aqueous waste. They will settle sufficiently to permit discharge of a clarified effluent. Together with very fine product waste, these oxides constitute the bulk of the sludge from the waste treatment plant. This amounts to 0.1 Kg per 1000 Kg of product.

Alcohol is recovered for reuse by distillation. The aqueous phase remaining is the principal waste product of the plant.

FIGURE II-5
SOLUTION POLYMERIZATION
(ZIEGLER PROCESS)

Source: EPA publication EPA-440/1-74-010-a

The polymer slurry is processed by steam stripping, filtration, drying, extruding and pelletizing as is done for the solution process, and the hydrocarbon solvent is purified by distillation. A small quantity of aqueous waste is recycled to the alcohol unit.

Products obtained by this process include:

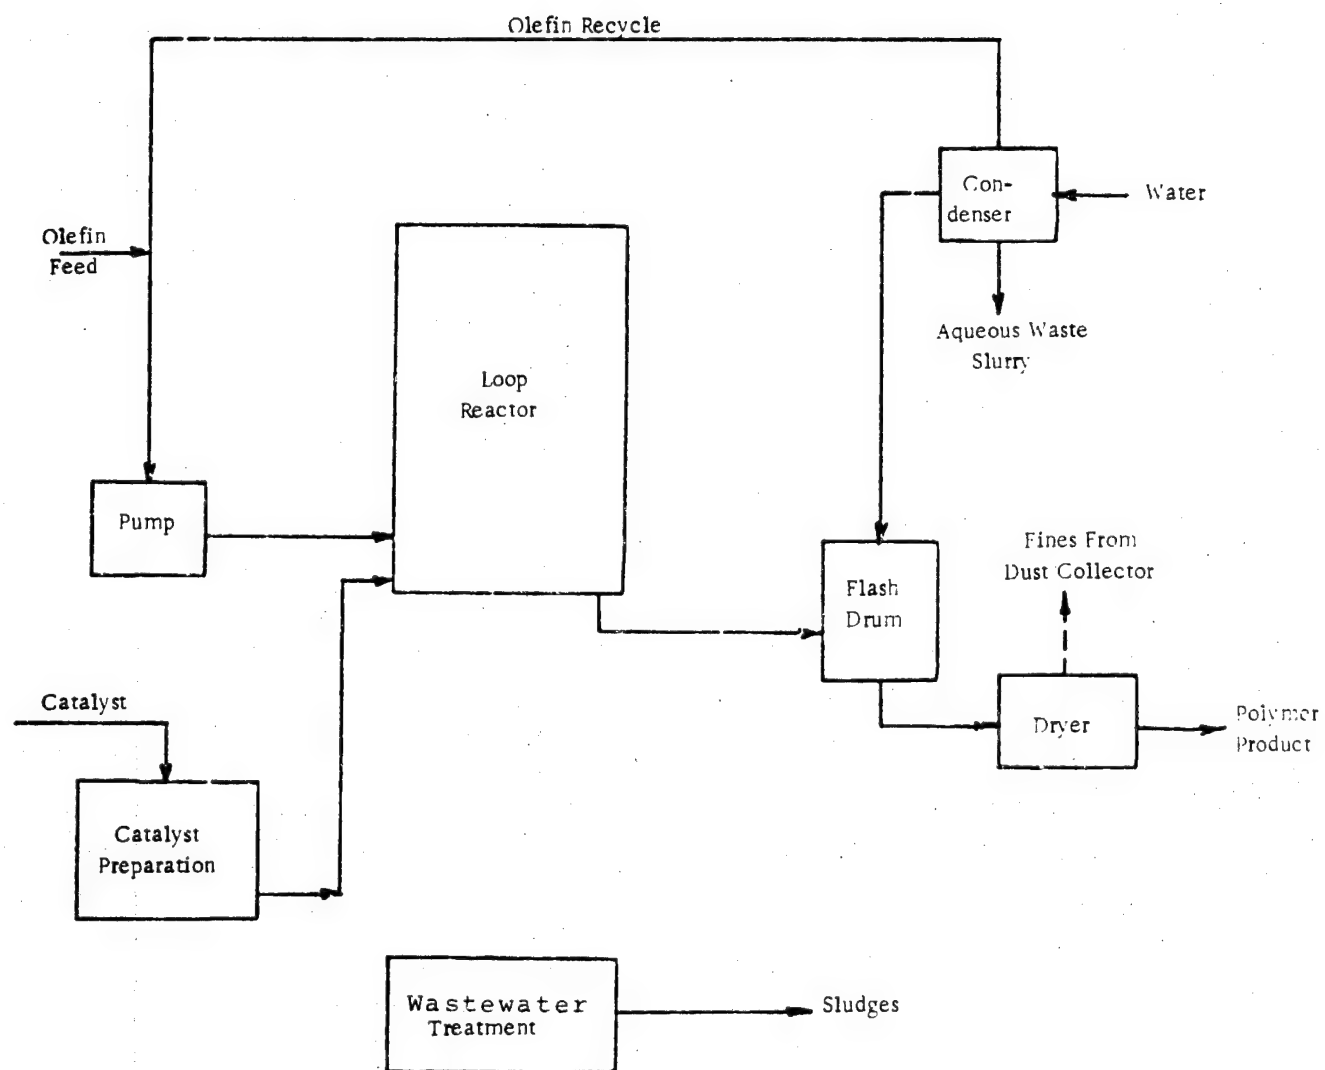

- . High Density Polyethylene
- . Styrene Butadiene Rubber (SBR)
- . Polybutadiene
- . EPM-EPDM Rubber
- . Butyl and Chlorobutyl Rubber
- . Polypropylene
- . Polybutene
- . Copolymers of this family of monomers.

3.2.1.3.3 Particle Form Process

The problems of the solution process for polyolefins have to a large degree been overcome in a newer version called the particle form process, and the method has a growing commercial acceptance for the manufacture of high density polyethylene, polypropylene and copolymers (Figure II-6). There have been three major changes:

- . The catalyst (ethylene and comonomer) system has been modified so that it can be incorporated into the polymer. Its activity has been increased to the point that special measures for catalyst removal are unnecessary for many grades of polymer.
- . The hydrocarbon solvent system has been modified so that the polymer is not as soluble and is obtained as a slurry rather than a solution in the diluent.
- . Special design loop-reactors have been developed which allow the polymerization system to operate under good control of reaction conditions and at satisfactory rate.

FIGURE II-6
PARTICLE FORM POLYMERIZATION
FLOW DIAGRAM

Source: EPA publication EPA-440/1-74-010-a

In this method, catalyst and olefin feed are added to the reaction mass which is circulated continuously through the loop reactors. A stream is also withdrawn continuously from the reactor to a flash drum. Polymer is removed from the bottom of the flash drum, dried, and processed through an extruder pelletizer as with the other methods.

The vapor stream from the flash drum is scrubbed to remove polymer fines. This step produces a small quantity of wastewater. Both unreacted olefin and recovered diluent are then separated from the overhead stream and recycled to the reaction step.

The products and waste streams of these processes are essentially the same as reported previously (3.2.1.3.1 and 3.2.1.3.2).

3.2.2 Non-Olefinic Polymers Used In Fiber Manufacture

There are three main groups of polymers that are used in non-cellulosic fiber manufacture: acrylics and modacrylics, polyamides (nylons) and polyesters. Olefinic polymers are also used in the manufacture of fibers (in particular polypropylene) but the production of these has already been described. The spinning methods are described in Section 3.2.5.

A series of figures are provided to illustrate the processes and waste streams discussed under non-olefinic polymers used in fiber manufacture.

- . Figure II-7 -- Acrylic and Modacrylic
- . Figure II-8 -- Nylon "6" (Polyamide)
- . Figure II-9 -- Nylon "6,6" (Polyamide)
- . Figure II-10 -- Polyester Resin

3.2.2.1 Acrylics and Modacrylics

The bulk of this production is carried out by a suspension or emulsion process (Figure II-7). The monomer acrylonitrile, together with comonomers such as vinyl chloride⁽¹⁾ are added to a reactor kettle at a ratio of about 10 parts of water to one part of monomer. The reaction is initiated by redox catalysts and initiators such as ammonium persulfate, sodium metabisulfite and sulfuric acid. The common practice is to meter the reactants and water continuously into the reactor and to obtain the polymerized material as an emulsion overflowing out of the reactor. The emulsion is filtered continuously to remove large size agglomerates (gels or "fish eyes").

The filtered material is directed to monomer recovery where the free monomer is stripped and returned to the reactor. The stripped suspension is then separated by centrifugation, followed by a water wash, dried in a continuous oven and stored for sale to other processors or for captive use. The precatalyst is recovered. Generally, in multi-plant operations by a given company, one polymerization facility services the various spinning plants.

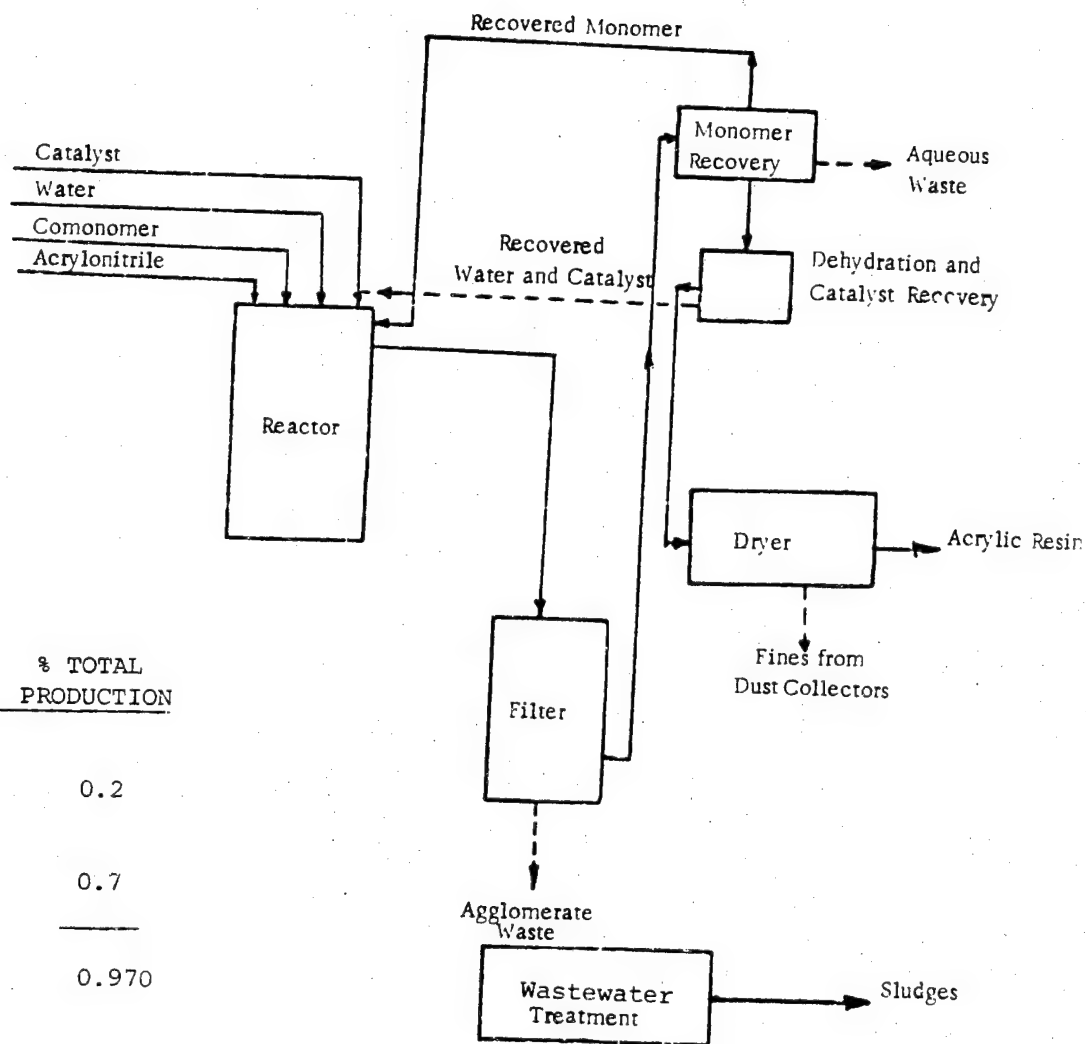

The most important source of wastes is the filtering process. The waste stream consists of the polymer itself, sometimes contaminated with unreacted comonomer.

The monomer recovery still bottoms are essentially water based and are disposed to wastewater treatment facilities. They contain low molecular weight polymer, estimated at 7 kg per 1000 kg produced.

3.2.2.2 Polyamides

There are two main polyamide resins used in fiber production; Nylon 6 and Nylon 6,6 (Figures II-8 and II-9). Nylon 6 is essentially a polymer of caprolactam, and Nylon 6,6 results from the condensation of hexamethylene diamine and adipic acid, which are reacted to form nylon salt.

There are two ways to polymerize Nylon 6. They differ essentially in how the unreacted caprolactam monomer is removed. In the wet method, polymerized chips are washed with water and the resulting caprolactam solution is eventually concentrated, after treatment with potassium permanganate, to a 70 percent solution. This final solution is separated into a bottom stream containing solid oligomers and high boiling liquids and reasonably pure caprolactam which is returned to process. Two solid waste streams are produced: the permanganate residue which is in the form of a solid and the still bottoms.

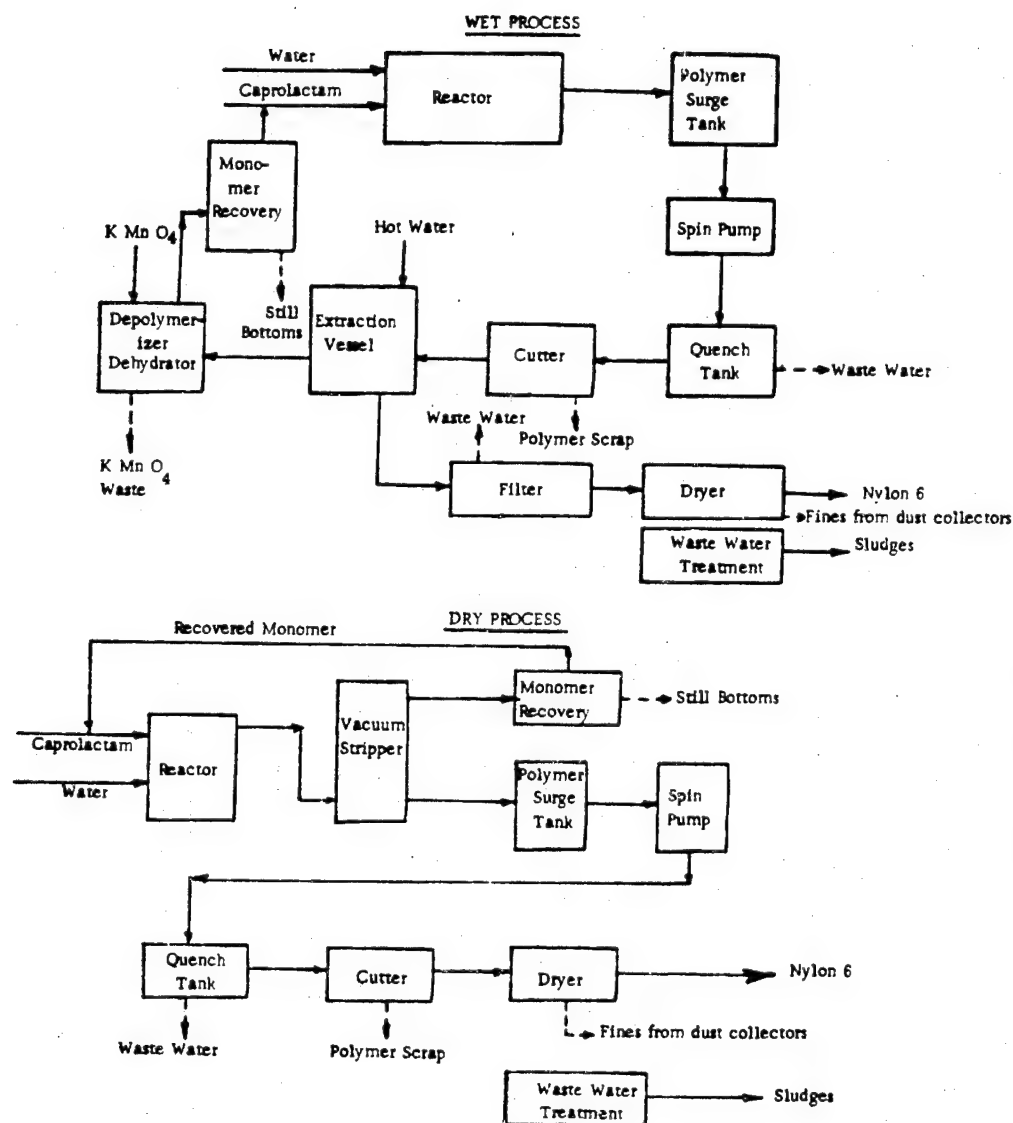

In the second, or dry process, the unreacted caprolactam is stripped from the molten polymer under vacuum. In this process, no waste stream is produced, except for equipment cleanings and ends of run.

To make Nylon 6,6, hexamethylene diamine is reacted with adipic acid to give a nylon salt solution which is decolorized with adsorbent charcoal. The salt is then mixed with water and acetic acid and polymerized in an autoclave with addition of delusterant (titanium dioxide). The resin is then band cast, chopped, blended and stored for shipment or local use in spinning operations.

A significant waste stream consists of a filter cake, which is a mixture of spent carbon, diatomaceous earth and nylon salt from the decolorizing operation. It amounts to 0.36 percent of the total production. Some of the wastewater streams from the pro-

cess contain large amounts (1%) of hexamethylene diamine. Though this material is readily biodegradable in the treatment facilities, it contributes to the biological sludge formed.

3.2.2.3 Polyesters

The polyesters used for fiber production are glycol terephthalates which polymerize to polyethylene terephthalate with the formation of recoverable ethylene glycol (Figure II-10). The primary reactant may be the ester, dimethyl terephthalate, in which case methanol is evolved during the esterification reaction preceding the polymerization. It is a frequent practice to return the glycol and methanol streams to the manufacturer. In this case, whatever still bottoms are associated with those streams are handled as part of the glycol or methanol production processes.

The catalysts used in polyester manufacture are reported to include acetates of cobalt, manganese and cadmium. These catalysts may obviously give rise to potentially hazardous waste streams, particularly in primary sludges of water treatment facilities. It was not possible to obtain data on these materials and no sludge production was reported.

Some manufacturers acknowledge the presence in their solid wastes of comparatively large quantities of zinc compounds. But zinc chloride is widely used as a solution agent for certain types of solution spinning and this may constitute a larger source of this ion than the polymerization operations.

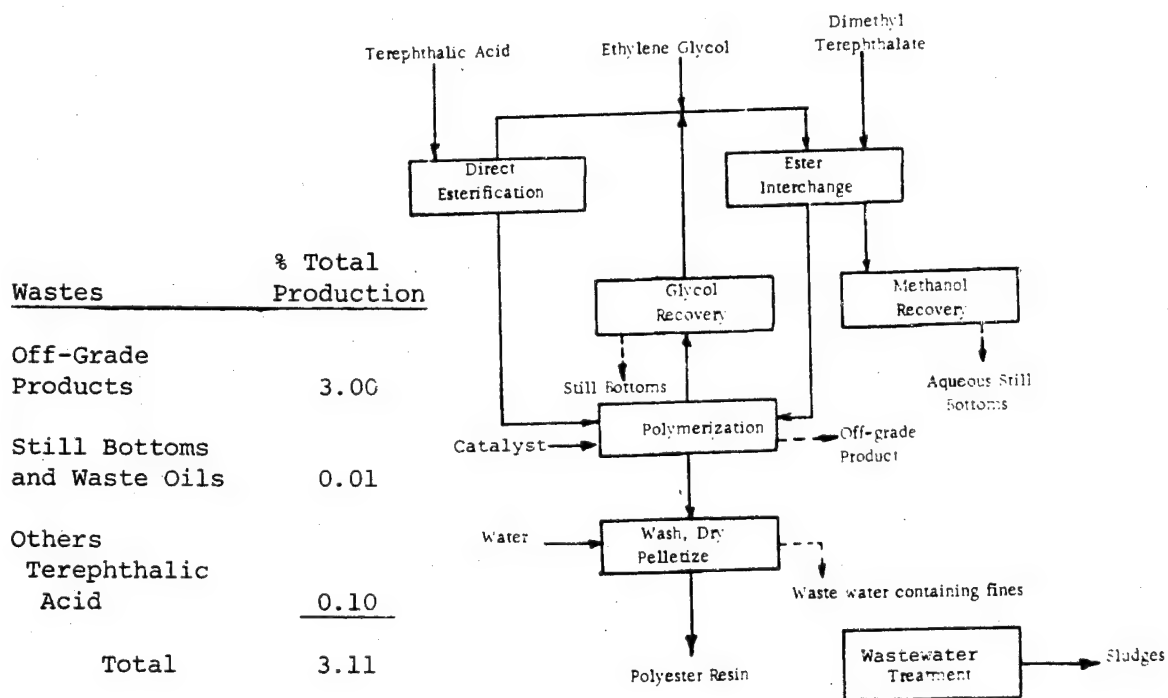

3.2.3 Non-Olefinic Polymers Primarily Used As Resins

A series of figures are provided to illustrate the processes and waste streams discussed under non-olefinic polymers primarily used as resins.

- Phenolic resins--Figure II-11
- Amino resins--Figure II-12
- Coumarone-Indene resins--Figure II-13

FIGURE II-10

POLYESTER RESIN FLOW DIAGRAM

- . Epoxy resins--Figure II-14
- . Alkyd resins--Figure II-15
- . Polyurethane--Figure II-16
- . Silicones--Figure II-17

The products in this group are arranged according to two criteria: production technologies and production volumes. The first three, phenolics, amino and coumarone-indene resins, are produced in specialized, identifiable facilities with relatively large yearly production. Within the group, the phenolic resins have the highest production volume. The last group, consisting of resins, epoxy, alkyds and polyurethanes and silicones are made in thousands of various formulations, in hundreds of locations with considerable differences in the size of plants, in the sophistication of equipment used and in the production technologies. The process descriptions for these resins are only illustrative. Furthermore, the significant variations mentioned above make a generalization of waste stream data infeasible.

3.2.3.1 Phenolic Resins

These resins are formed by reacting phenol, or a substituted phenol, with an aldehyde (Figure II-11). The industry produces two broad types of resins in this category: resols and novolaks.

The waste stream from these two processes consists of partially polymerized material, containing an excess of phenol, which appears as a suspension in the water distillates. As noted later, no satisfactory method of handling this waste stream has yet been devised. Some major manufacturers are reportedly at work on this problem, but consider the development of such a method to be a highly proprietary item.

3.2.3.1.1 Resol Manufacture

Molten phenol (Figure II-11) is fed to the reaction kettle, followed by formaldehyde. This serves to clear the lines of residual phenol. A catalyst solution of sodium hydroxide is then added and the kettle heated to about 60°C.

When the desired degree of polymerization has occurred, the kettle is cooled to about 35°C to inhibit further reaction. The caustic may be neutralized in the kettle with sulfuric acid at this time. The water from this distillation forms a concentrated waste of unreacted materials and low molecular weight resin.

The batch is dumped and, depending on the specific resin, the batch may be washed several times and a vacuum may be used during the dehydration cycle. It is important that molten resin be handled quickly to avoid its settling up to an insoluble, infusible mass, which would become a waste.

3.2.3.1.2 Novolak Manufacture

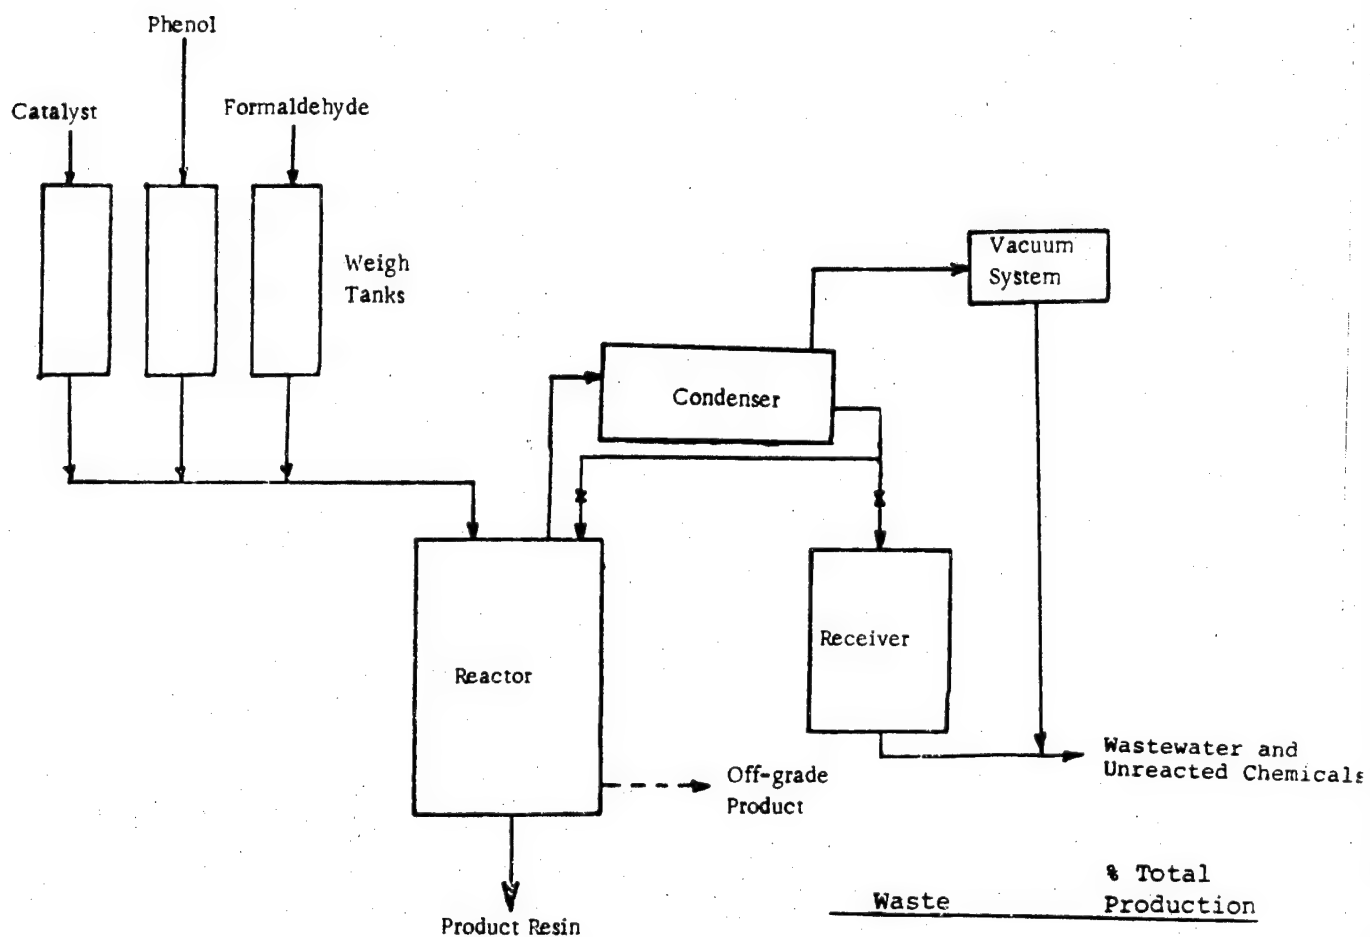

Novolak manufacture is almost identical to that of resol (Figure II-11). The major difference is that sulfuric acid is used as a catalyst. Because of this, vacuum reflex must be used to maintain a temperature of 85-90°C, which is slightly higher than for resols. The reaction continues for 3 to 6 hours at which time the condensate is switched to the receiver and water is removed by vacuum. The temperature goes to about 120-160°C. This reaction does not have to be cooled because polymerization is complete.

The product is allowed to solidify or solvents may be added to keep it in a molten form. If solidified, it is ground to powder or flake form before being shipped.

3.2.3.2 Amino Resins Manufacture

When formaldehyde is reacted with certain nitrogen containing organic chemicals, in particular urea and melamine, an amino resin is formed (Figure II-12). Typically, amino resins are manufactured in a standard batch polymerization process. Because many specialty grades are made, the batches are frequently small.

⁽¹⁾ Illustrative Data Only

Formaldehyde is put in the kettle and the pH adjusted to about 7.0-7.8. The catalyst, boric acid, is added and then the urea or melamine. The pH is adjusted again to near neutral. The reaction proceeds at 100°C under atmospheric reflux conditions for about 2 hours. Then, a vacuum is applied and the temperature dropped to 40°C for about 5 hours. The system is then put on total reflux and the pH adjusted to slightly alkaline. The material may either be shipped as a liquid or dried and powdered.

In some instances, formaldehyde is received in a pure state. In this case, there is a tendency for solid formaldehyde polymers to be produced--para-formaldehydes. These are highly flammable solids, giving off strong formaldehyde fumes. Bad batches, containing large excesses of unreacted formaldehyde, require disposal.

3.2.3.3 Coumarone-Indene Resins

The name of this group of resins is somewhat misleading. Initially, these resins were condensation products of a coal tar fraction consisting essentially of coumarone and indene. At present, the bulk of the production is based on the condensation of various reactive chemical species present in heavy petroleum distillates (boiling point in the range of 100°C to 250°C).

In summary, there are two groups of raw materials:

- . C-I crudes (coumarone-indene fraction of coal tar distillates)
- . Petroleum distillates.

Lighter fractions of petroleum distillates are used in the process as a diluent.

Coumarone-indene resins are manufactured by two basic methods:

- . Thermal polymerization
- . Solvent polymerization.

In thermal polymerization (Figure II-13), the raw materials are blended to a predetermined composition, then heated under pressure. After the polymerization has reached the desired point, the reaction is vented to a condenser where a distillate (sometimes called "inert") is recovered. The batch is then steam stripped under vacuum until the desired hardness is achieved. The resin is then transferred to packaging kettles.

The solvent process (Figure II-13) may take two forms depending on raw materials. If the C-I crudes are used as the starting material, acid and caustic washes are required to remove amines and phenols which are present in the crudes. This procedure is not required if petroleum distillates are the raw material. This is the only difference between the two forms.

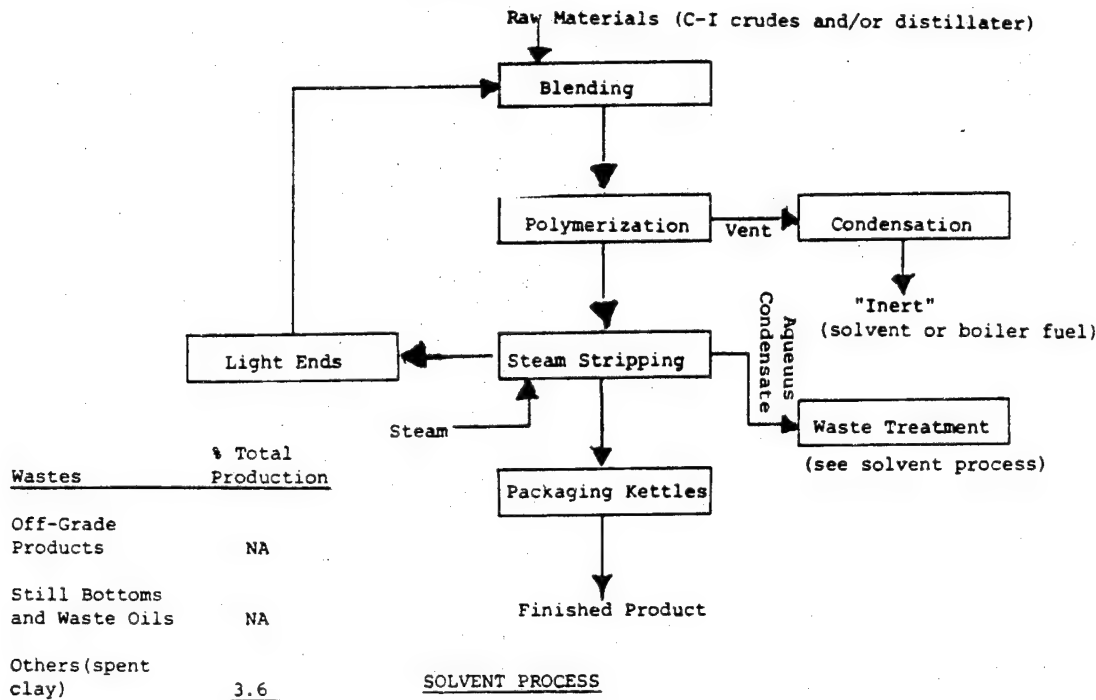

A polymerization catalyst is used. It is usually boron trifluoride. The mixture is then heated until the desired degree of polymerization is achieved. At this point, additional diluent and a mixture of attapulgit clay and lime are added to the reactor. The mass is then filtered in a continuous vacuum filter to remove the clay and lime.

The filtrate undergoes fractional distillation. The low boiling fractions are recycled as diluent or burned as boiler fuel. The middle fractions constitute the desired product and the still bottoms are sold as a lower grade product.

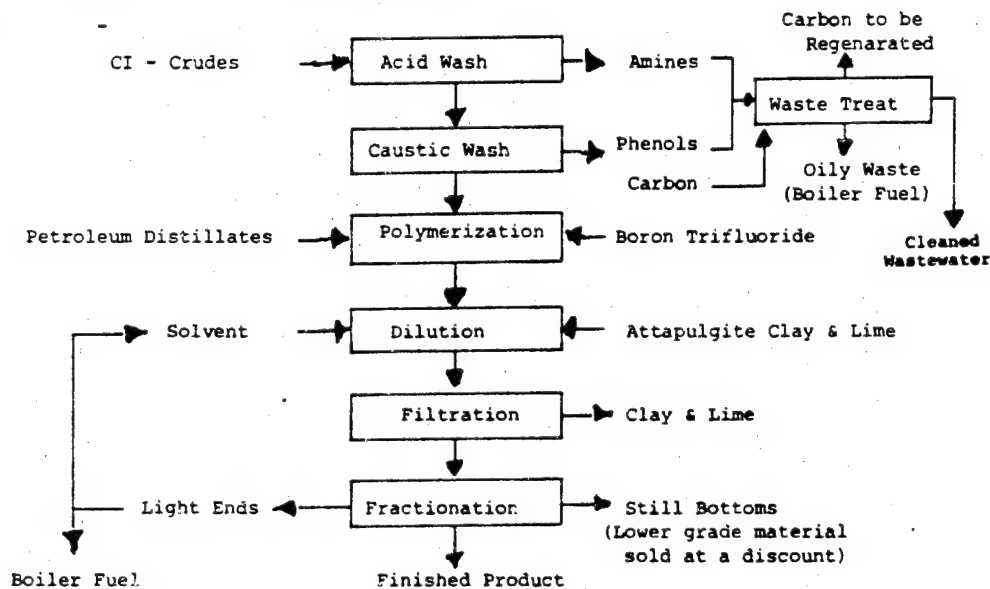

The waste streams from these operations are the clay/lime cake, which may contain some fluorine and some boron, and the products from wastewater treatment. In most installations, the wastewater treatment includes a trap which collects the waste oils. These are used as fuel for the boilers. The final wastewater treatment consists of carbon adsorption. The spent carbon is returned to the supplier for regeneration. The amount of carbon and oily wastes varies according to the product mix. The waste clay/lime residue is a function of the amount of resin produced by the solvent process.

FIGURE II-13
COUMARONE-INDENE FLOW DIAGRAM

THERMAL PROCESS

SOLVENT PROCESS

3.2.3.4 Epoxy Resins

The bulk of the epoxy resins are produced by the condensation of epichlorohydrin with bisphenol A (4,4'-isopropylidenediphenol). However, formulation variants involve the use of other polyols, i.e., aliphatic glycols. Sometimes epichlorohydrin is reacted with Novolak type phenolic resins, thus transforming them into epoxy type products.

The final desired properties are obtained by achieving a combination of basic resin formulation of the degree of polymerization desired and of curing agents. These are added at the point of use, so that the final products are made by mixing a resin component with a curing component, very often in equal or nearly equal volumes. The curing agents cover a broad range of chemical species: amines, polyamides, acids and anhydrides, or even resins of the phenolic or the polyamino groups.

The bulk of the commercial production is in the so-called lower molecular weight group (M.W. 360-650) which is liquid at room temperature. Higher molecular weight material has a consistency varying from "taffy" (M.W. 800-1,000) to brittle solid (M.W. 2,000-8,000). The highest molecular weight material (M.W. 5,000-8,000) melts at 145-155°C.

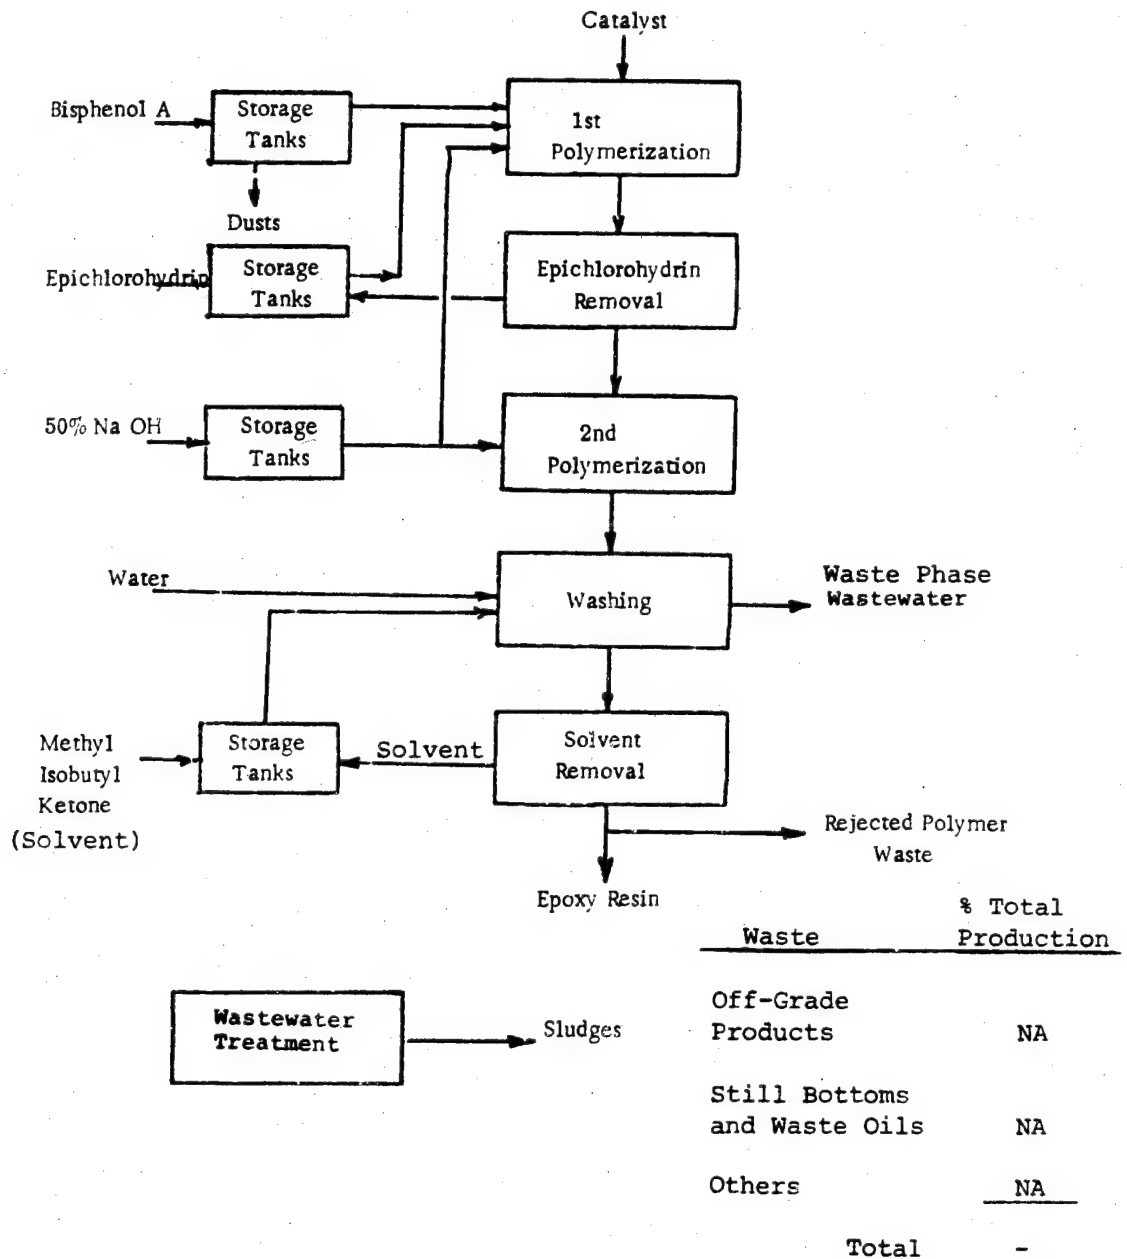

The production processes vary enormously in technology and capacity. The processes described in the following paragraphs are only illustrations. The formulations of the catalysts, which are used to promote the desired straight line reaction over an undesirable branching type of reaction, are highly proprietary.

3.2.3.4.1 Continuous Process

The process described here (Figure II-14) is a two-step process. Bisphenol A, epichlorohydrin, catalyst and 50% caustic soda solution are continuously fed at appropriate rates to a first polymerization chamber. The material then passes continuously to epichlorohydrin removal where

FIGURE II-14

EPOXY RESIN FLOW DIAGRAM
(CONTINUOUS PROCESS)

Source: EPA publication EPA-440/1-74-010-a

excess epichlorohydrin is removed and returned to the storage area. The material stripped from epichlorohydrin goes to a second polymerization chamber, where an additional amount of 50% caustic is introduced at the appropriate rate. The material leaves the chamber to go to a washing operation where water and methyl isobutyl ketone are added to provide a two-phase system which is continuously separated, the water phase being discarded. A final step consists of solvent removal. The solvent is then recycled to the washing operation. The waste streams in this process are unusable off grade product and wastewater which usually has to be treated by a conventional treatment system.

3.2.3.4.2 Batch Process

In this variant of the process, the operations of first and second polymerization, epichlorohydrin removal, washing and solvent removal are carried out successively in the same vessel. However, in this case, at the end of the operations the temperature is such that the resin is in the molten state at between 70°C and 150°C. This process is sometimes referred to as the batch fusion process. The molten resin is allowed to solidify and then can be flaked or ground to a powder. The waste streams are the same as in the continuous process. Proprietary catalysts are believed to be discarded in solution in the wastewaters.

3.2.3.5 Alkyd Resins

Chemically, the alkyl resins are the products of the reaction (esterification) of various polyhydric alcohols (polyols) with polybasic acids (e.g., phthalic or malic acid) and unsaturated aliphatic acid (fatty acids).

Alkyds are made generally in liquid form and are further compounded and modified at their point of use. There are innumerable formulas and ingredient combinations.

Individual production units are usually quite small and often associated with larger manufacturing facilities, principally in the paint and coatings industry SIC 285.

The problem with this particular group of polymers is that the esterification reaction between acid and hydroxyl (alcohol) groups (-CHOH and -COOH) releases a mole of water. Since the reaction is reversible, this water has to be removed to allow the reaction to continue to proceed in the desired esterification direction. Two main processes (Figure II-15) are used to achieve this end:

- In the solvent process, the reactants are introduced into a polymerization kettle. A solvent, such as xylene, is continuously added to the kettle and allowed to distill out as an azeotrope carrying the water vapor. In a solvent recovery unit, the water is separated as an aqueous stream and the solvent returned to the kettle.

After completion of the polymerization, the resin is thinned with a solvent (xylene) in a thinning tank and the mixture is filtered to remove solid waste (off grade product).

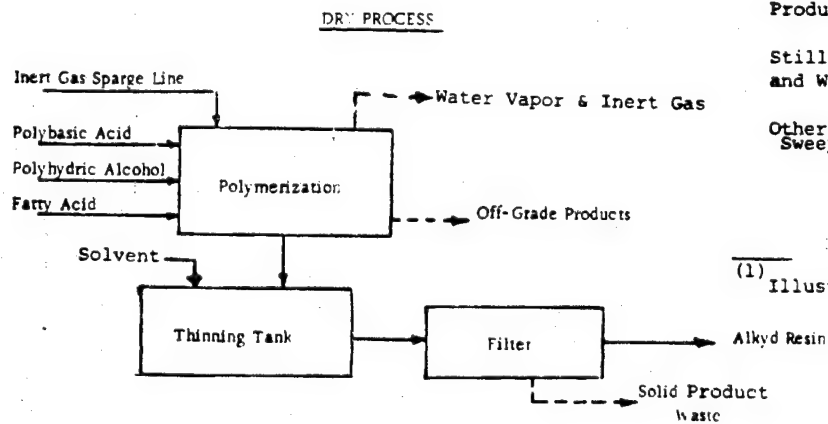

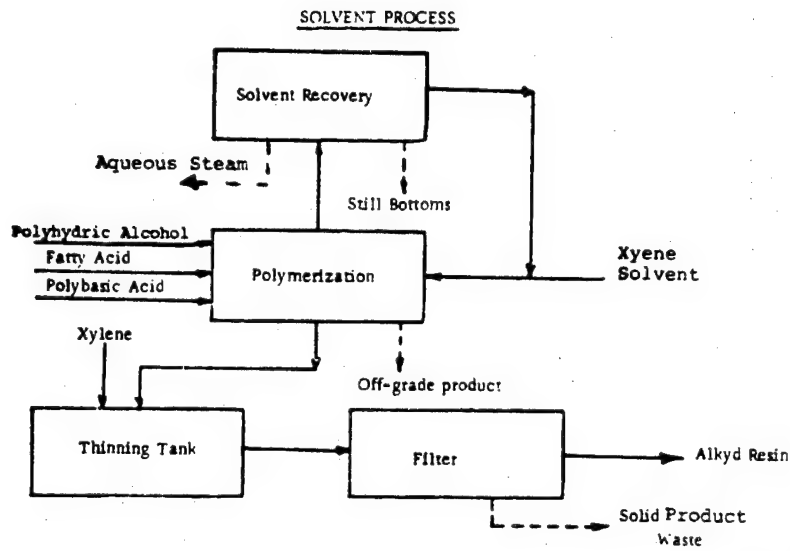

- In the dry process, also known as fusion process, the materials are introduced into a polymerization kettle, a stream of inert gas is sparged through the mixture to carry out the water vapor formed. When polymerization is complete, the resin is transferred to a thinning tank, solvent is added and the mixture is filtered.

3.2.3.6 Polyurethanes

Polyurethanes are obtained by reacting di-isocyanates or polyisocyanates with polyols or polyamines (Figure II-16). Many of these reactions can be carried out at the point of use in completely unsophisticated equipment amounting to little more than a kettle with a stirrer. Formulations encompass literally thousands of varying combinations of ingredients, mostly proprietary.

FIGURE II-16

POLYURETHANE FLOW DIAGRAM

Source Foster D. Snell, Inc.

The only production of polyurethanes by SIC 2821 appears to be that of "pre-polymers." These prepolymers are complex mixtures of partially polymerized products and usually of highly proprietary formulation.

The prepolymers are classified as reactive and non-reactive. These names refer to the subsequent steps necessary to complete polymerization. Reactive prepolymers can polymerize by action of atmospheric moisture. The mechanism of polymerization of the non-reactive prepolymers can be straight air oxidation or may require the addition of a reactant mixture.

Most of the production is carried out directly from the monomers (often referred to as compound A and compound B) by plants outside the SIC 2821. For instance, production is carried out by automotive accessory manufacturers (cushions, padding), by paint plants or by appliance manufacturers (i.e., refrigerators). In addition, the global production figure is only about 50,000 Kkg per year (100 million lbs./year).

3.2.3.7 Silicones

Silicone rubber and resins are made by the polymerization of several silicone monomers or oligimers. The backbone of the polymer is based on Si atom(s) rather than on C atom(s). The silicones are usually manufactured in extremely complex plants, which often incorporate in their operation the production of the monomers themselves. In addition, the products of polymerization are arbitrarily classified between segments 2821 and 2822 of the SIC 282 group and segment 2869 of the SIC 286 Industrial Organic Chemical Industries.

Silicones are produced in only a few plants in the United States. The production methods, processes and even products and by-products are highly proprietary.

The process descriptions and flow diagrams presented in this study represent information developed by direct discussion and interviews with industry representatives and are limited by considerations of possible inadvertent disclosure of confidential information.

In very general terms, there are two initial parallel operations resulting in products classified in SIC 2821 and 2822:

- . A bulk polymerization step producing gums and hydrolyzed silanes
- . An emulsion or suspension polymerization process producing silanol fluids.

In addition, there are further processing operations:

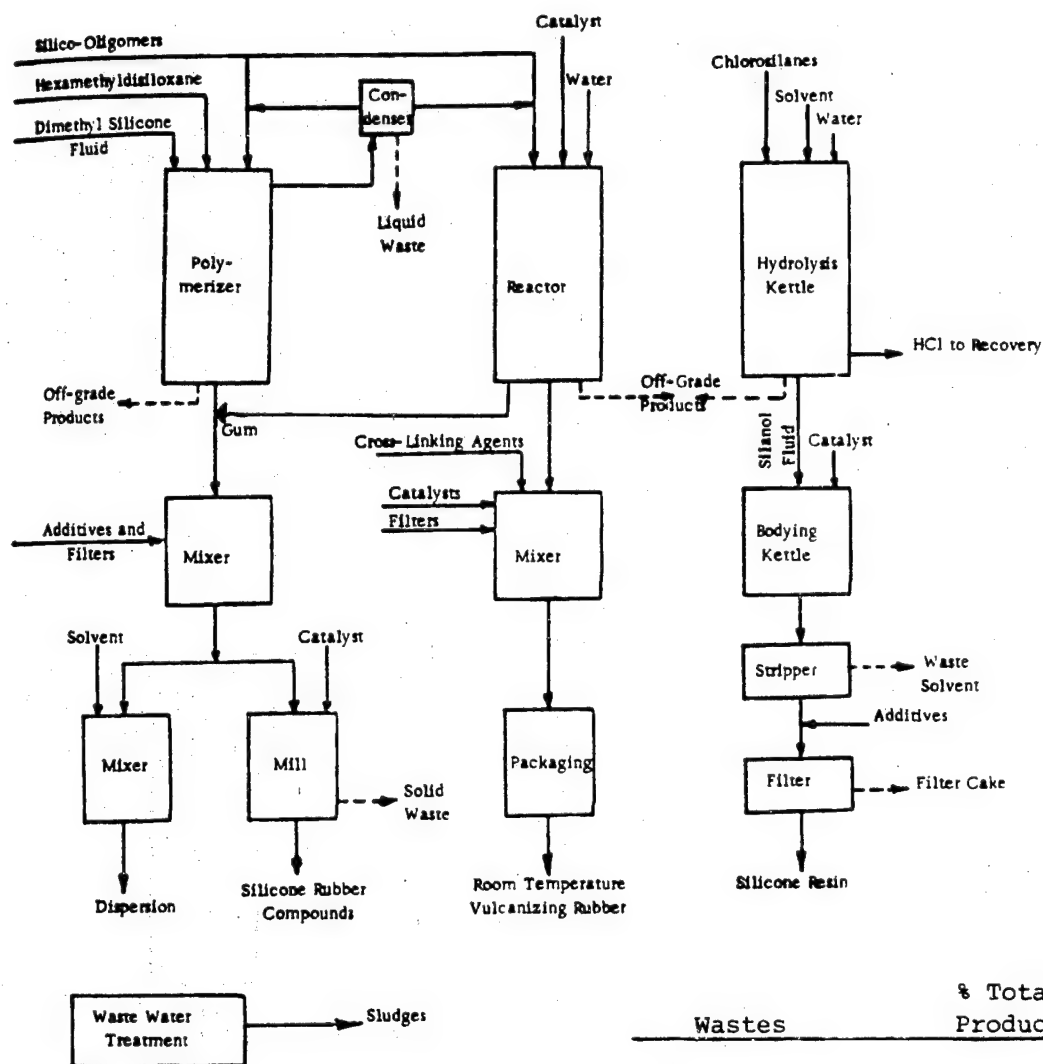

- . The gums produced by bulk polymerization are compounded as silicone rubber plastics.
- . The gums are disposed in solvent and marketed as dispersion (plastisols).
- . Further processing of by-product streams of bulk polymerization leads to the production of room-temperature vulcanizing rubber (RTVR).

An alternative route leading to silicone resins starts with chlorosilane compounds. These compounds are hydrolyzed in a reactor containing water and an immiscible solvent. The water layer containing hydrochloric acid is discarded and the solvent layer containing the hydrolyzed silanes is polymerized to silicone resins by addition of catalyst and heating. Figure II-17 summarizes the process involved.

The following descriptions are illustrative and are intended to key some reported waste streams, the exact origin of which is proprietary.

FIGURE II-17

3.2.3.7.1 Gum Production

Silicone gum is produced by polymerization of a mixture of silico-oligomers in the presence of a catalyst. Volatile compounds are evolved during the operation and are partly returned to the process after condensation and partly disposed of as liquid wastes. Prior to being fed to the reactor, some of the oligomers are dried by adsorption on silica gel type molecular sieves. These are discarded from time to time giving rise to a waste stream. Cleanings of the equipment and off-grade unusable products are also disposed of. The product gums are used as raw materials for the production of silicone rubber.

3.2.3.7.2 Silicone Rubber Compounding

One type of silicone rubber is produced by compounding gums, additives and fillers on a Banbury mixer. The product is further compounded (refined) on roll mills. These operations produce a liquid waste stream and a solid waste stream.

3.2.3.7.3 Silicone Resin Production

The starting materials for this production are a mixture of chlorosilanes and solvent. The first step involves the hydrolysis of the chlorosilane by addition of water. This is followed by gravity or centrifuge separation of the water layer. The next step is the polymerization step, sometimes called bodying. This step is carried out in an agitated kettle with addition of a catalyst (sometimes a salt of zinc) and by heating. The solvent is then stripped off and usually disposed of as waste. At this point, some resins are simply cooled and flaked. Other resins are obtained by addition of various proprietary ingredients. When the additives have dissolved, the resin is filtered over filter presses and allowed to cool. The waste streams in this process are, in addition to the waste solvent already mentioned, the filter cake and some scrap resin--either off-grade product or from cleaning the reactors.

3.2.4 Cellulosic Products

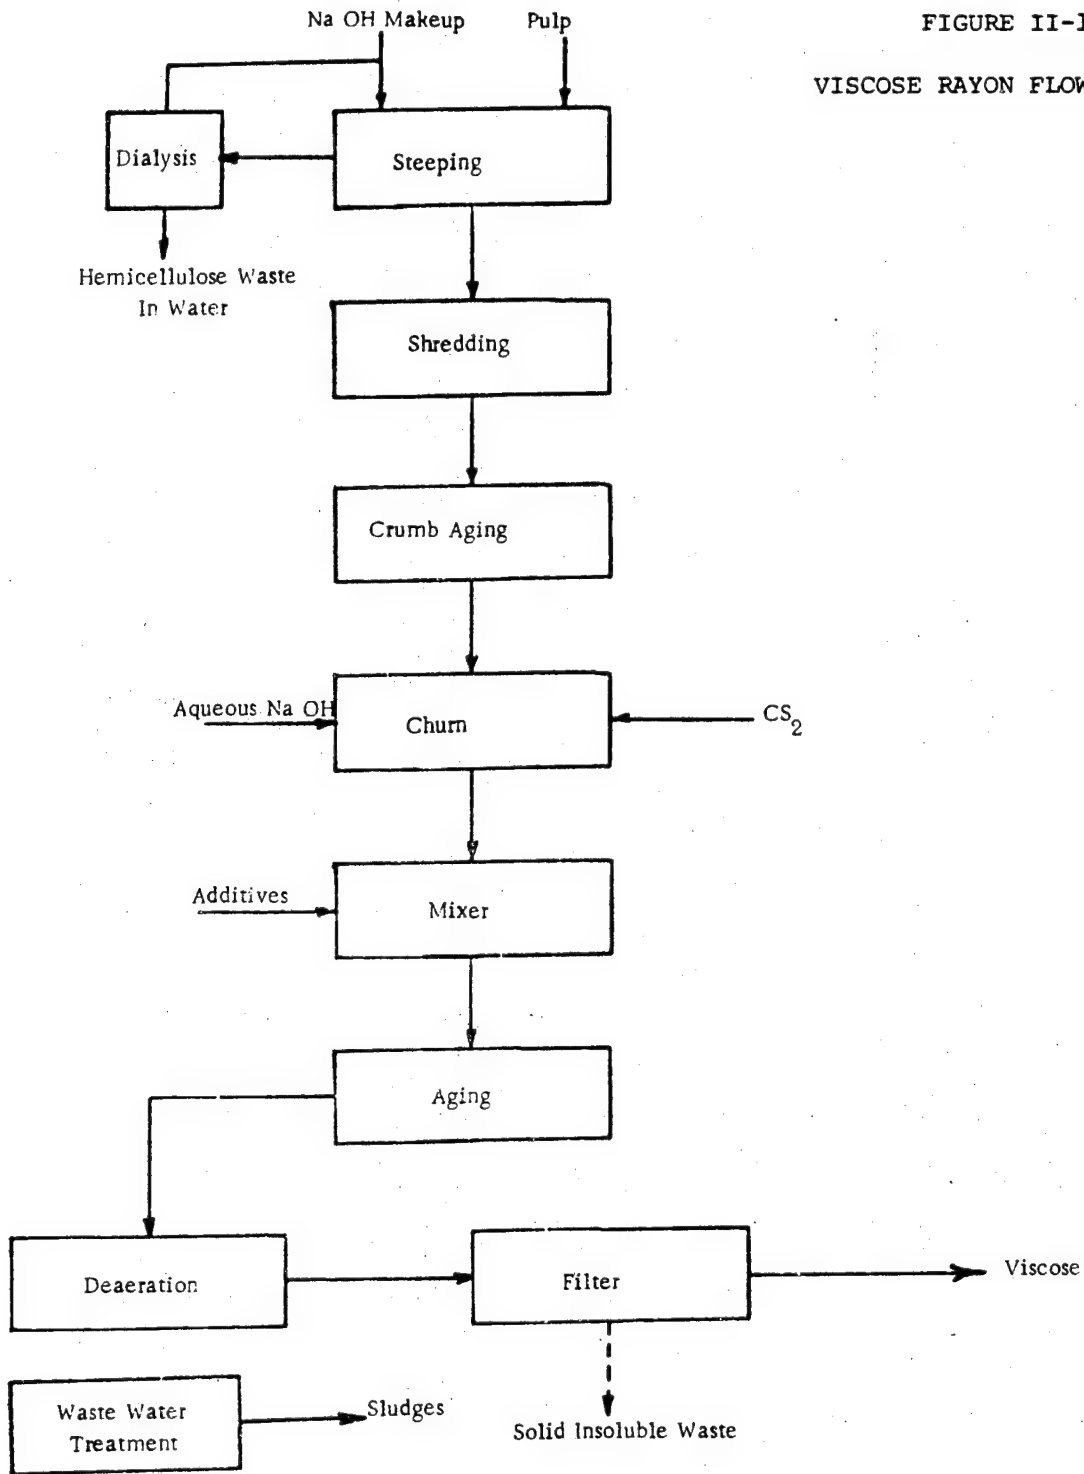

Chemically, there are two fundamental groups of cellulosic products: the rayons and the acetates. At present, the bulk of the production of these materials is for fiber manufacture. However, there is still a significant production for films (cellophane and photographic films of acetate). The rayons are basically reconstituted cellulose. The acetates are reaction products of cellulose with acetic anhydride. The most recent form is known as the triacetate. In the U.S. the term "rayon" includes man-made textile fibers and filaments composed of regenerated cellulose. The term "acetate" has been adopted to indicate man-made textile fibers and filaments composed of cellulose acetate.

3.2.4.1 Rayon

Chemically, rayon is a modified cellulose, which is the main constituent of wood pulp. Since 1910 to 1911, the rayon in the United States has been produced by the Viscose process (Figure II-18). Wood pulp (pulp) is slurried in a caustic solution (NaOH), then the excess caustic is expressed and goes to a dialysis step to separate the hemicellulose formed by reaction of caustic with some of the cellulose. The treated caustic solution is returned from the dialysis to the steeping operation. The treated pulp from the steeping process goes to a shredding operation which forms crumbs. The crumbs are aged in the crumb aging operation under controlled conditions. The crumbs are reacted in a churn with aqueous NaOH (dilute caustic) and carbon disulfide (CS₂) to form cellulose xanthate. Proprietary additives are added in a mixer and a second aging process takes place. Then, the slurry goes to a deaeration step, followed by a filtering step, and a viscose solution is obtained that can be used for a casting operation to form cellophane on a spinning operation to form fibers.

The waste streams from this operation consists of solutions of hemicellulose and a solid waste, which is in effect an off-grade product. Difficulties in meeting water effluent guidelines have resulted, and continue to result, in the decline of rayon production in the United States. Numerous large production facilities have been closed down.

FIGURE II-18
VISCOSE RAYON FLOW DIAGRAM

Source: EPA publication EPA-440/1-74-010-a

3.2.4.2 Acetates

There are two basic types of acetates produced in significant quantities. These materials differ only in the degree of acetylation. When 92% or more of the hydroxyl groups in cellulose are acetylated, the product is referred to as cellulose acetate. There are no significant differences in the manufacturing processes of these materials. A flow diagram of the process is presented in Figure II-19.

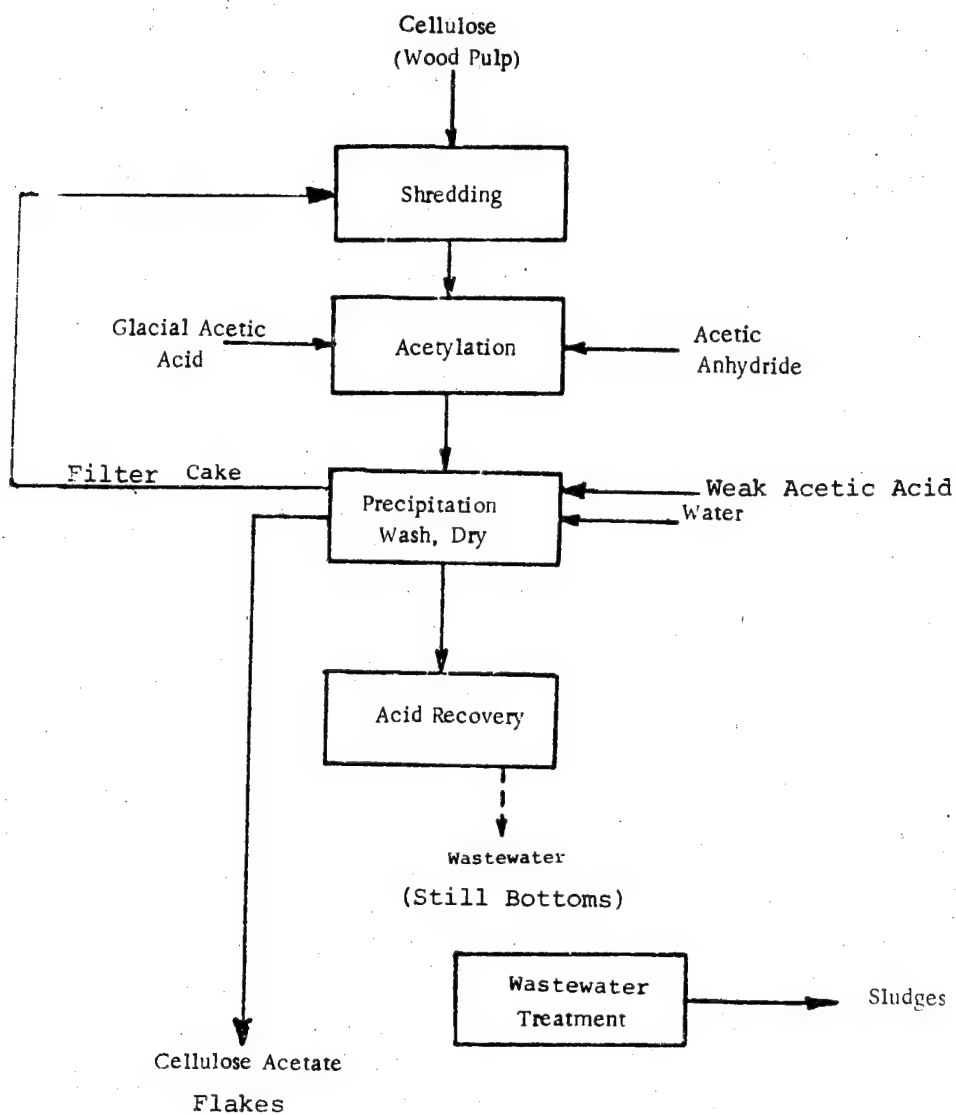

After shredding, the wood pulp goes to the acetylation process where it is treated first with acetic acid to activate the cellulose. This is then fed to acetylation reactors where it is treated with acetic anhydride. A clear viscous solution of cellulose acetate in water is obtained.

The product is recovered as a flake by precipitation with a weak acetic acid solution and countercurrent water wash. The flakes are dewatered on a vibrating screen and dried in an oven. The water stream from the vibrating screen is filtered and the filter cake is returned to the head of the process; therefore, a waste is not created. The filtrate is sent to acetic acid recovery. The acid recovery is performed by extractive distillation with a proprietary solvent. The still bottoms include a concentrated solution of magnesium sulfate, soluble cellulose products and a trace of the solvent.

3.2.5 Spinning Processes

Spinning operations are significantly different from the polymerization processes described in the previous sections. Spinning differs from polymerization both in terms of the equipment used and the type of physico-chemical changes occurring. In many instances, a form of further polymerization takes place; however, this polymerization is in the form of cross-linking. Cross-linking is similar in chemical terms to the vulcanization of rubber which is discussed in Volume III of this report.

FIGURE II-19
CELLULOSE ACETATE RESIN FLOW DIAGRAM

Source: EPA study (Contract No. 68-01-0030)

Fundamentally, spinning is an extrusion process (Figure II-20) in which the polymer is forced through spinnerets either in solution form or as a melt. The spinning operation may also be an extension of the basic polymerization process. When the polymer is in solution form, it is called a dope. The solvent can be water, an aqueous salt solution or a water miscible organic liquid.

There are three basic spinning methods:

- . Melt spinning where the extruded fiber solidifies by cooling
- . Wet spinning in which the fiber solidifies by coagulation in a bath
- . Dry spinning where the fiber solidifies by evaporation of the solvent.

Subsequent treatment may involve stretching, washing, bleaching, lubricating, crimping and dyeing. The order of these steps varies according to the products treated and the result desired.

Spun fibers include monofilament (a single, untwisted synthetic filament) and yarns, staples and tow. Staple and tow are produced by chopping the fibers to desired lengths. Staple in general has shorter fiber lengths than tow and is used in further spinning operations characteristic of typical textile operations. Tow is used in such applications as filters for cigarettes. Monofilaments and yarns are directly processed into fabrics, ropes, etc.

A synoptic presentation of spinning processes is provided in Table II-38 for the most common fibers. Processing steps and wastes generated are discussed in greater detail in the following paragraphs for each of these fibers. The discussion is organized in the order of production volume.

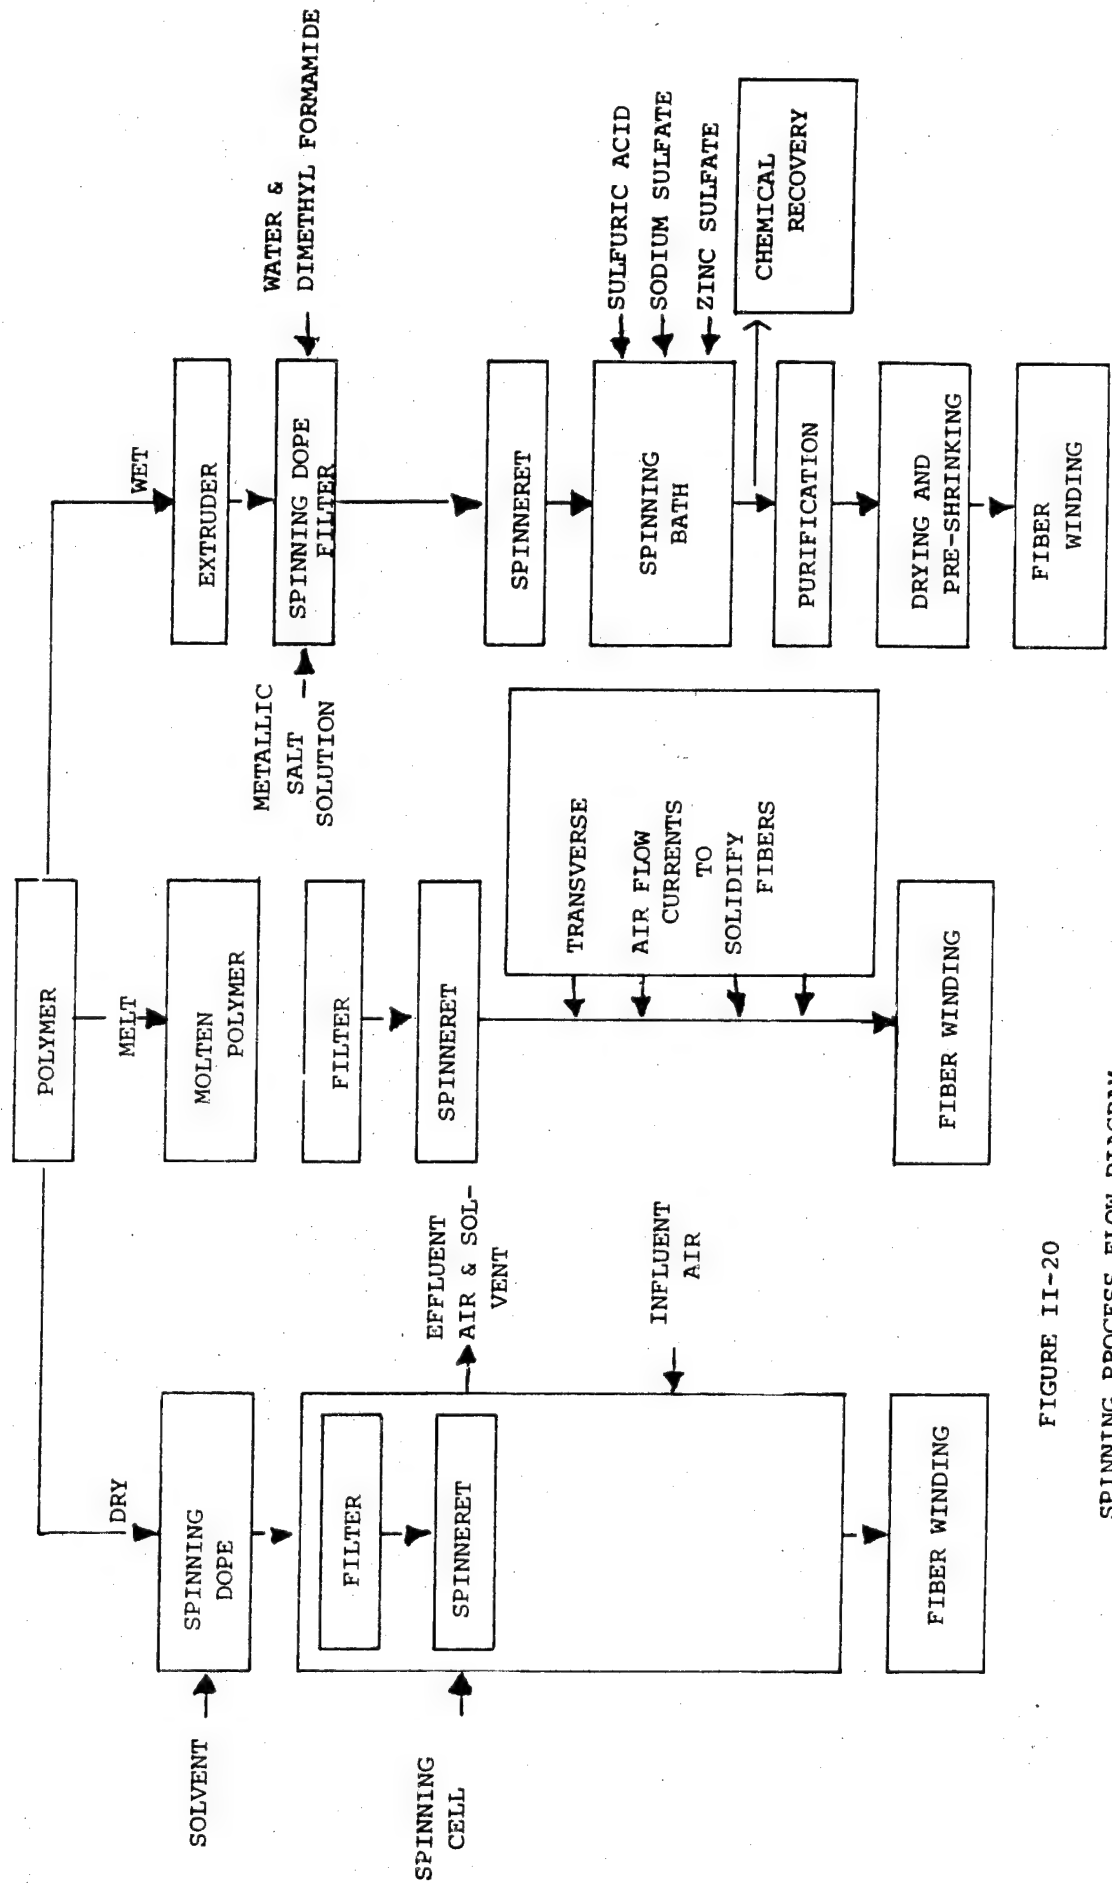

FIGURE II-20
SPINNING PROCESS FLOW DIAGRAM.

TABLE II-38

SYNOPTIC DESCRIPTION OF SPINNING PROCESSES

<u>Fiber</u>	<u>Method</u>	<u>Solvent</u>	<u>Bath</u>	<u>Secondary Bath</u>	<u>Further Treatment</u>	<u>Bath Reclaim</u>

3.2.5.1 Polyester And Nylon Spinning

The same process (melt spinning) is used for the spinning of polyester and of nylon fibers. The polymers (polyester and nylon) are produced by the processes described in the previous subsections dealing with polyester and polyamide production.

The polymer is heated to its melt point and filtered through sand or metallic filters. The filters are directly ahead of the spinnerets through which the filtered melt is extruded. The extruded melt is cooled under controlled conditions, and solidified fibers form subsequently.

Polyesters are dry stretched while nylon is stretched in steam or hot water baths. Sometimes, the fibers are crimped and vegetable oil finishes may be applied.

The wastes generated by this process are mostly represented by off-grade material. In many cases, this waste may be depolymerized or returned to the polymerization processes. For example, terephthalic acid can be removed from off-grade polyester fiber and returned to production. Filtering sand is also a waste.

Metallic filters in most cases do not represent a significant waste because they may be regenerated via highly proprietary techniques.

3.2.5.2 Acrylics

There are two methods which can be used for the spinning of acrylic fibers: wet spinning and dry spinning.

Wet spinning involves two variants:

- In one, the resin is dissolved in concentrated solutions of mineral salts. Here, the coagulation process consists of leaching out the metal salt(s) from the spun fiber by means of water baths. The salts are usually recovered.

- In the other variant, a water miscible solvent, for example dimethylformamide, is used to prepare the spinning dope. The solvent is leached out by water baths.

- . The dry spinning process involves the use of an organic solvent. A recovery step is required. Recovery steps usually involve adsorption of the solvent on activated carbon followed by steam stripping of the saturated carbon and final recovery by distillation or decantation.

From time to time, the carbon beds are replaced. If a significant stream is thus generated, the carbon is returned to the manufacturer for reprocessing. In the case of spinning from a metal salt solution, the metal ions eventually end up in the wastewater treatment sludges. One of the principal salts thus used is reported to be zinc chloride and, therefore, the wastewater treatment sludges contain significant amounts of zinc.

Subsequent steps may involve steam stretching, dyeing, finishing, crimping and settling. No significant wastes are generated.

3.2.5.3 Modacrylics Spinning

Modacrylics differ from acrylics chemically because they are copolymers.

The process used to spin the modacrylic fibers are similar to those used for acrylics and may indeed use the same equipment at certain locations. As an example, the spinning of Dynel is discussed here.⁽¹⁾

Dynel is a copolymer of acrylonitrile and vinyl chloride prepared by the emulsion process described in paragraph 3.2.2.1. The

⁽¹⁾ Kirk-Othmer, Encyclopedia of Chemical Technology, 2nd Edition, Volume 17, pp. 168-209, Intersciences Publisher, New York (1967).

resin is dissolved in acetone and extruded through a spinneret into an aqueous coagulating bath. After washing to remove the solvent and after the application of a finish, it is stretched from five to fifteen times its original length. Next, the fiber is annealed or baked by exposing the yarn to hot circulating air. This treatment relieves strain and reduces subsequent shrinkage. Finally, the fiber is crimped, cut and baled.

Off-grade material constitutes the only significant waste streams generated in spinning of modacrylics.

3.2.5.4 Rayon Spinning

The rayon is manufactured by the process described in section 3.2.4.1, in the form of a solution of cellulose xanthate. This solution, after filtration and deaeration, is pumped through spinnerets into a coagulation bath consisting of a solution of sodium sulfate and magnesium sulfate acidified with sulfuric acid. There are, however, numerous variants in the composition of the xanthate solution and of the bath, which are used to improve the characteristics of the finished product.

The solidification of the rayon fiber in the coagulation bath is a two-step process. As the cellulose xanthate coagulates, there is an accompanying chemical transformation from the xanthate salt to pure cellulose. This is called regeneration and it precedes coagulation.

The net effect of the addition of chemicals to the xanthate solution and/or to the bath is to increase the time lag between these two steps, resulting in an improved tenacity of the fiber. Among the additives reported in the literature are substituted ethylene diamines and dithiocarbamates. Metallic salts, such as zinc chloride, are also used as additives. ⁽¹⁾

(1) Kirk-Othmer, Encyclopedia of Chemical Technology, 2nd Edition, Volume 17, pp. 168-209, Intersciences Publisher, New York (1967).

The complex nature of the bath associated with the spinning of rayon requires extensive water treatment facilities. The mineral salts, such as zinc chloride, are precipitated out as sludges. These sludges constitute the main waste stream from rayon spinning and may contain leachable metal ions.

Other waste streams that are generated consist of off-grade material which is discarded or returned to the head of the viscose production stream.

3.2.5.5 Cellulose Acetate And Triacetate Spinning

Cellulose acetate and cellulose triacetate fibers are produced by a dry spinning process. In this process, cellulose acetate or triacetate, prepared by the process described in section 3.2.4.2, is dissolved in a solvent to form a dope.

- . In the case of cellulose acetate, the solvent used for the manufacture of the dope is acetone.
- . In the case of triacetate, the best solvent is a mixture of methanol and methylene chloride.

The dope is then spun through a spinneret, as shown in Figure II-20.

The solvents are evaporated from the spun material by means of a hot air stream and adsorbed on carbon. The evaporated solvent is regenerated by steam stripping of the saturated carbon followed by distillation. No waste stream is generated by solvent recovery. The only further processing step is reported to be fiber lubrication.

*

*

*

The wastes associated with spinning operations are shown in Table II-39.

TABLE II-39

4. WASTE CHARACTERIZATION FOR THE PLASTIC MATERIALS AND SYNTHETICS INDUSTRY

For the purpose of waste characterization, no valid reason exists to maintain the SIC segmentation of SIC 282. A more reasonable segmentation is between the polymerization and the spinning operations since these topics are more descriptive of the actual conditions in the industry.

The previous section described the processes used and waste streams generated in the segments of SIC 282. The present section:

- . Identifies and quantifies general waste streams found in our industrial analysis through field visits, interviews and literature studies.
- . Pinpoints the streams which have been found to be potentially hazardous.
- . Quantifies the wastes for the years 1974, 1977 and 1983.

Qualification of waste streams were presented in Table II-37 for the polymerization operations and in Table II-39 for the spinning operations.

4.1 Waste Stream Characterization In Polymerization Operations

The identification and quantification of the waste streams, particularly in an industry group like SIC 282, is complicated by several factors. Some of these factors are as follows:

- . Location of the production facilities -- e.g., single or integrated, and, if integrated, with that
- . Relative importance of the process at a given location of the production facilities
- . Unquantifiable and variable distribution of products among various production processes -- e.g., emulsion and solution SBR
- . Unquantifiable and variable distribution of raw materials in such groups as epoxy, alkyds, polyurethanes, silicones.

Another important factor is the presence of two types of waste streams:

- Well-defined waste streams bearing a fairly constant quantitative relationship to the production volume, e.g., still bottom
- Fortuitous waste streams, characterized by a lack of consistent magnitude, composition, and dependency on extraneous factors, e.g., product changes, human errors, instrument failures.

The field study indicated that the fortuitous waste streams constitute the bulk of the streams, both in number and degree of importance. For instance, it was found that a very important waste stream was that of the irrecoverable off-grade product. The sources of this stream include ends and beginnings of runs, reactor cleanings, spillages, and production upsets.

Further complicating the characterization of some waste streams is the highly proprietary nature of some of the materials involved. In certain product groups (e.g., alkyds epoxy resins, acrylics, and modacrylics), the monomers themselves are proprietary. Almost invariably the exact nature of the catalysts cannot be divulged. Spinning bath compositions are also proprietary.

Within these restrictions, a review of the individual waste streams reported by the interviewees during the field visits is presented in the following paragraphs. The order of presentation is according to decreasing production volume of the particular group of polymers. Subcategories (e.g., polyvinyl acetates) are discussed with the main group, regardless of their individual production levels.

4.1.1 Polyesters

The bulk of polyester production is for use in the fiber industry. Much of the production is captive.

The polyesters most widely used are glycol terephthalates, which polymerize to polyethylene terephthalate with production of ethylene glycol as a by-product (Section 3.2.2.3 Figure II-10; Process Flow Diagram). The ethylene glycol is either processed at the polymerization site or returned to the supplier. In many instances, the primary reactant may be dimethyl terephthalate, in which case a by-product of methanol is produced by transesterification. Usually, this also constitutes a valuable stream which is returned to the supplier.

The literature⁽¹⁾ indicates the use of acetates of cobalt, manganese or cadmium as catalysts. However, the published flow diagrams do not involve a catalysts removal step, nor have any of the interviewees reported such a step. Wastewater treatment facilities are incorporated at most production locations and the metallic ions associated with the process may appear in the sludges.

Some manufacturers indicate the presence in their solid wastes of large quantities of zinc compounds. However, zinc chloride is used as a solution agent for certain types of wet spinning operations, and this may constitute the largest source of zinc ion. It is to be noted also that polyesters, as esters, are readily hydrolyzed so that depolymerization of off-grade waste products are returned to production.

Other wastes include off-grade products still bottoms, waste oils and unreacted terphthalic acid.

4.1.2 Polyamides

The waste stream from Nylon 6 production (Section 3.2.2.2, Figure II-8) consists of manganese hydroxide mud from purification of the recovered caprolactam stream and the still bottoms from caprolactam distillation.

The main waste stream from Nylon 6.6 (Section 3.2.2.2, Figure II-9) production is the spent carbon from the decolorization step. Another stream contributed to by this operation is the biological sludge formed as part of the biological degradation of hexamethylene diamine, one of the starting materials. Off-grade products may account for 3 Kg/KKg of production (0.3%).

(1) Kirk-Othmer, Encyclopedia of Chemical Technology (2nd Edition), Vol. 16.

4.1.3 Acrylics And Modacrylics

In acrylic production (Section 3.2.2.1, Figure II-7), the main waste stream (agglomerate wastes) results from filtration after the polymerization reaction has taken place. The waste can contain large particulates of the polymer referred to as gels or "fish eyes." Monomer recovery still bottoms are another source of waste. These wastes are aqueous and are treated in the wastewater treatment facilities. They may contribute oligimers to the wastewater sludge.

The operation at one specific plant is said to involve a moderately toxic metal ion which is precipitated as a primary sludge. To disclose the ion or the operation would, however, be contrary to the competitive interests of the interviewee.

4.1.4 Low Density Polyethylene

The production technology of this product (described in Section 3.2.1.2.2) is reasonably uniform. The only waste streams identified are:

- Spent lubricating oils from the compressors, which may be found in other polymerization and spinning processes
- Oligomers from the monomer recovery
- Off-grade products, which may amount to 1.0% (10 Kg/KKg of production).

The production does not involve the use of identifiable catalysts.

4.1.5 High Density Polyethylene

The variation of the processes used in the production of polyethylene resins contributes to the difficulty in quantifying the waste streams. It is known that the bulk of the high density polyethylene is still manufactured by variants of two solution processes: the Phillips process and the Ziegler process (Section 3.2.1.3. Figures II-4, II-5). However, no quantitative data can be obtained as to the production distribution among the two processes because such information would be proprietary. Yet, there are very significant differences in the waste streams produced by each process.

To complicate matters further, a new variant of these processes, the particle form process (Section 3.2.1.3.3., Figure II-6) has recently been introduced. From the standpoint of waste streams, the most important aspect of this latter process is that there is no catalyst removal step. In the Ziegler process, an aqueous catalyst removal step is involved which eventually produces aluminum and titanium oxides. In the Phillips process, the catalyst is separated as a finely divided solid consisting of a ceramic-type mixture of alumina and chromium oxides. Because of the ceramic nature of the catalyst, there is no chromium leachate.

In addition to these streams, there are off-grade products and, in the Ziegler process, bottoms from aqueous alcohol recovery. This latter stream goes to the wastewater treatment facilities where it contributes to the production of biological sludges.

4.1.6 SBR Rubber

Two methods are used in the production of SBR rubber: The solution polymerization process and the emulsion polymerization process.

If the solution process is used, the washed butadiene stream has to be dried in an absorbent. The adsorbent can be regenerated over many cycles; but it must eventually be discarded, and it thereby creates a waste stream. When Ziegler type catalysts are used in the solution process (Section 3.2.1.3., Figure II-5), the typical alumina and titanium dioxide sludges are also produced, constituting another source of wastes.

In the emulsion process (Section 3.2.1.1., Figure II-2), wastewater treatment sludges constitute another waste stream. A waste stream, at certain locations, consists of the alkaline wash used to remove catechol, which stabilizes the butadiene stream. Both emulsion and solution processes contribute to this type of waste stream.

Additional waste streams may be generated where master batching constitutes a significant proportion of the production. These include:

- . Carbon black dusts (sometimes in the form of a wet scrubber sludge.)
- . Waste additive oils resulting from spillages or production upsets. These are often caught in special traps or pits.

Storage tanks and equipment cleanings also contribute to waste streams, as do off-grade products.

4.1.7 Polyvinyls

Polyvinyl chloride and polyvinyl acetate are the main products in this group. Polyvinyl chloride is produced in greater quantity. The two main processes that are used are suspension or emulsion polymerization and bulk polymerization.

Waste streams generated in suspension or emulsion polymerization of polyvinyl chloride include:

- . Off-grade finished product, which can be as high as 2.0% of total production.
- . Wastewater sludges, amounting to 11 Kg/KKg of production (1.1%) and possibly including vinyl chloride monomer from reaction cleanings
- . Fines from polymer separation
- . Sweepings, which can include dusts (although with current OSHA requirements, dust production should be reduced)
- . Scrap pellets.

Waste streams constituted in polyvinyl acetate production include off-grade products (discolored resin chunks), which are estimated to be 10 Kg/KKg of production. In addition waste streams may be generated by:

- . Still bottoms containing oligomers and vinyl chloride dissolved in vinyl acetate
- . Filtered latex waste when polyvinyl acetate is processed as the latex
- . Vinyl acetate copolymer.

4.1.8 Polypropylene

Polypropylene is produced by a variety of process variations quite similar to those used for high density polyethylene (Section 3.2.1.3.2, Figure II-5). The general waste streams associated with polypropylene and high density polyethylene are similar. However, as with high density polyethylene, the variability contributes to the difficulty in quantifying the waste streams.

Off-grade products are estimated to account for 0.5% of total production. Still bottoms and waste oils may account for 10 Kg/KKg of production, thus constituting another source of waste. Amorphous polypropylene may, under adverse economic conditions, constitute a portion of the still bottoms. However, this material can be used for certain applications, e.g., adhesives.

In those plants using variations of the Ziegler process, an aluminum hydroxide waste stream is generated. Newer variations (particle form process, Section 3.2.1.3.3., Figure II-6) utilize more efficient catalysts that can be left and incorporated into the finished product. Other sources of waste streams include:

- . Fines water streams and dust collectors
- . Wastewater treatment sludges
- . Aqueous wastes with polymer solids
- . Scrap flakes.

4.1.9 Other Synthetic Rubbers

The waste streams encountered in production of such rubbers as neoprene, EPM, EPDM and polybutadiene are similar to those encountered in SBR production (Section 3.2.1.1., Figure II-2). These would include:

- . Wastewater treatment sludges
- . Scrap
- . Fines in sludge water
- . Fines from dust collectors.

In addition, spent adsorbent and spent catalyst constitute a waste stream with these other synthetic rubbers. At one location, vanadium waste stream is produced from the used catalyst; however, the metal is reduced to 1 ppm when diluted in other plant wastewaters. The still bottom and waste oil streams are estimated to be 60 Kg/KKg of production of neoprene.

4.1.10 Phenolic Resins

The phenolic resins (Section 3.2.3.1.1., Figure II-11) present waste streams which deserve considerable attention. Water is generated during the reaction and is distilled off from the reactors. There is entrainment of oligomers, unreacted phenols, and other organic components in this very significant water stream. This source of waste is estimated (on a wet basis) to be about 500 Kg/KKg of product produced with an organic content of 5% to 15%. These wastes also contain large amounts of phenols, substituted phenols and cresols in addition to other organic components. As previously mentioned in Section 3.2.3.1., no satisfactory method of handling this waste stream has been devised. These wastes are essentially hazardous and are discussed in Section 4.3.

Other significant waste stream sources are composed of off-grade product (which is estimated to be 8 Kg/KKg of product produced) and wastewater sludge which is estimated to be 60 Kg/KKg and which may contain partially unreacted product.

4.1.11 Amino Resins

The process flow diagram for amino resins was previously presented in section 3.2.3.2. Figure II-12). Waste stream identification includes:

- . Off-grade material constituting an estimated 10 Kg/KKG of product produced
- . A significant proportion of production in still bottoms and waste oils (42 Kg/KKg)
- . Filter cake from the production of liquid resins.

In addition, wastes are generated from bad production batches, usually caused by unreacted formaldehyde. One solvent (methanol) may also be part of wastes produced, depending upon the efficiency of the system.

4.1.12 Coumarone-Indene

These resins (Section 3.2.3.3, Figure II-13) are almost insignificant in terms of production volumes as compared to the large volume of polyethylenes in vinyl chlorides. They are practically free of waste streams. The petroleum distillates may be utilized as boiler fuel. Still bottoms (lower-grade material) are sold at a discount.

The major waste stream consists of spent clay (36 Kg/KKg of production). This results from those processes that use boron trifluoride as a catalyst during the polymerization step. Attapulgate clay and lime are used to remove boron/fluorine and spent catalyst. The resulting spent mixture is filtered out and consists of about 60% clay/calcium hydroxide and 40% organic residue. The boron trifluoride or its decomposition products are likely to be in this waste stream.

4.1.13 Alkyd Resins

The products containing alkyd resins are extremely numerous and vary greatly. Therefore, generalizations based on the necessarily limited field investigations are of limited validity. Section 3.2.3.5 previously described general production (Figure II-15).

Wastes usually associated with alkyd resin production include:

- . Off-grade product (1 Kg/KKg of production)
- . Sweepings from warehouse wastes.

Bulk shipping of monomers in a production facility is the exception rather than the rule. Therefore, when solid, these monomers contribute significantly to the composition of warehouse wastes and represent a measurable fraction (0.1 Kg/KKg of production) of the production volume.

4.1.14 Epoxy Resins

These resins (Section 3.2.3.4, Figure II-14) are condensation products of epichlorohydrin, bisphenol A and other co-monomers. The observations made for the alkyds (in Section 4.1.13) apply equally well to this group of products.

The identifiable, but highly variable waste streams, could not be quantified but include:

- . Off-grade products
- . Off-grade raw materials
- . Still bottoms
- . Waste solvents (xylene).

4.1.15 Polyurethanes

The bulk of the production (described in Section 3.2.3.6, Figure 16) is performed at the manufacturing site where end-use products are made. Prepolymers are centrally manufactured in some plants in equipment which is sometimes even used for the manufacture of other groups of products, e.g., alkyds or epoxy. This equipment consists of batch reactors equipped with condensers which can work either as reflux or distillation condensers. The waste streams consist of washings, filter cakes, oligomers and solvents.

4.1.16 Silicones

As previously discussed in production processing of silicones (Section 3.2.3.7, Figure II-17), specific quantification of waste streams in silicone production is difficult. The waste streams include off-grade products which constitute an estimated 54 Kg/KKg of production. Still bottoms and raw material waste oils are estimated at a 58 Kg/KKg of production. Other estimated wastes include spent adsorbent and scrap (33 Kg/KKg of production).

Additional sources of waste stream generation include:

- . Waste solvent from silicone resin production
- . Filter cake used in a filtering step of silicone resin production.

4.1.17 Cellulosic

The waste streams from the viscose rayon process are essentially aqueous solutions, semi-solids (hemicellulose), fine slurries and sludges (Section 3.2.4.1, Figure II-18).

In the production of acetate and triacetates (Section 3.2.4.2, Figure II-19), the waste streams also include recovered acetic acid streams, which are usually reused in process or recovered for other purposes. Heavy concentrations of magnesium sulfate salts are also encountered. Cellulosic sludges are also produced.

4.2 Waste Stream Characterization In Spinning Operations

The spinning processes produce essentially three types of wastes (Figure II-20):

- . Various types of off-grade products at various stages of manufacture
- . Sludges from the treatment of waste baths
- . Still bottoms from solvent recovery.

In the following paragraphs, the specific nature of the waste streams associated with the various fibers and the various spinning methods are discussed in more detail. As usual, the discussion follows the order of decreasing importance in terms of weight processed.

4.2.1 Polyester Spinning Wastes

Because these products are generally spun from the molten state and because the material which has to be discarded for one reason or another can either be remelted or depolymerized, off-grade product wastes are insignificant. The waste sand, where sand filtration is used ahead of the spinneret, constitutes an insignificant stream.

A stream of waste finishes exists in some operations. This stream has been reported as being recovered in oil traps at a wastewater treatment facility.

Finally, a stream of triethylene glycol is sometimes produced from cleaning operations. It can usually be recovered.

4.2.2 Nylon Spinning

Nylon is spun from the molten state. The only waste streams from the spinning and finishing operations are said to be irrecoverable waste fiber and yarn, biodegradable and non-biodegradable finishing oils. In addition, a small stream of lubricant from various pieces of equipment is encountered in some installations.

4.2.3 Acrylic And Modacrylic Spinning

From the standpoint of waste generation, at least three widely different methods of spinning acrylics have been reported. Two methods are variants of the wet spinning process and one is a dry spinning method. The significant factor in the wet spinning process is the type of solvent used to form the dope. In certain instances, the acrylic material is dissolved in high concentrations of metal salts in water. In another variant, a water miscible solvent is used. Obviously, the wastes are quite different, depending on what process is used.

Large amounts of sludges containing metal ions have been acknowledged at several locations. A frequently mentioned ion has been zinc. On the other hand, some other installations (or some lines in the same plant) use different processes, e.g., dry spinning. In this case, a volatile solvent is used rather than a metal salt solution, still bottoms may be obtained and also biological sludges, if there is a biological treatment. It is difficult, therefore, to generalize the waste streams since distribution of the production across the three methods is not known. The dry spinning method is used for some modacrylics and is said not to produce any significant waste other than off-grade material.

4.2.4 Acetate And Triacetate Spinning

The spinning of acetate and triacetate fiber involves the dry spinning methods and exhibits the characteristic waste streams of this method. The main waste stream is off-grade material which can be hydrolyzed and returned to process.

4.2.5 Rayon Spinning

The spinning of rayon involves complex baths which have to be periodically readjusted or cleaned. Considerable wastewater containing high concentrations of all kinds of salts, organic and mineral compounds is generated. Extensive wastewater treatment is required with production of large amounts of sludges, which may contain leachable metallic ions.

In addition, warehouse dusts and sweepings may be generated in the handling of chemicals constituting the baths or added to the dope formulation. The use of such materials as diamines and dithiocarbamates has been reported. Large amounts of zinc salts are also reported to be used.

4.3 Potentially Hazardous Waste Streams And The Criteria For Their Classification

This section addresses streams which are designated as potentially hazardous when rated against the criteria of toxicity, flammability, etc. The streams identified as potentially hazardous include:

SIC 2821 -- Plastic Resins

- Wastes from phenolic resin production
- Amino resin waste streams
- Antimony and manganese catalyst waste from polyester production⁽¹⁾
- Still bottoms from solvent or monomer recovery in:
 - .. ABS-SAN resins
 - .. Polystyrene
 - .. Polypropylene
 - .. Silicone
- Warehouse dusts from alkyd production

⁽¹⁾ Polyester waste stream is listed under SIC 2821 to reflect the fact that the stream is generated at the polymerization step. It is understood that a considerable amount of polyester production occurs in SIC 2824.

- . SIC 2822 - Synthetic Rubber
 - Still bottoms from solvent or monomer recovery in
 - .. SBR via the solution process
 - .. Polybutadiene rubber
 - .. Neoprene rubber
- . SIC 2823 -- Cellulosic Manmade Fibers
 - Diamine and dithiocarbamate dusts and powders from rayon production
 - Wastewater treatment sludges from rayon production
- . SIC 2824 -- Non-Cellulosic Manmade Fibers
 - Zinc containing sludges from the spinning of acrylics and modacrylics.

By and large, company personnel in the plants visited are acutely aware of the potentially hazardous nature of the streams identified by the study team.

4.3.1 Criteria For The Classification Of Waste Streams As Potentially Hazardous In The Plastic Materials And Synthetics Industry

A potentially hazardous waste stream refers to any waste or combination of wastes which pose a substantial present or potential hazard to human health or living organisms because such wastes are suspected of being:

- . Toxic (including carcinogenic)
- . Flammable or explosive
- . Corrosive or reactive
- . Biologically magnified or persistent.

These types of hazards represent four out of five basic hazardous characteristics of wastes which were established in EPA's report to Congress, Disposal of Hazardous Wastes. The fifth characteristic, radioactivity, does not apply to the wastes generated by SIC 282.

According to the mandate given to Foster D. Snell, Inc., by EPA, detailed original toxicological, chemical and biological investigations to determine the potential for hazard creation by the literally thousands of substances in these industries which may become wastes was not a requirement. Instead, reliance on published sources which are compendia of much of the required information was the preferred approach. The sources chosen were:

- . Reference 1 -- Dangerous Properties of Industrial Materials (4th Ed.) N. Irving Sax (New York: Van Nostrand Reinhold Company, 1974).
- . Reference 2 -- Clinical Toxicology of Commercial Products (3rd Ed.) Gleason, Gosselin, Hodge and Smith (Baltimore: The Williams & Wilkins Co., 1969).
- . Reference 3 -- A Study of Hazardous Waste Materials, Hazardous Effects and Disposal Methods, Booz, Allen Applied Research, Inc., United States Environmental Protection Agency (Contract #68-03-0032) (Cincinnati, Ohio: 1972).

For the purposes of this study, oral toxicity was accepted as the basis for defining a toxic substance because more data are generally available to support published conclusions based on this parameter. Hazardous rating scales from these publications are presented in Appendix A, Methodology. Information from these sources were supplemented by the companies interviewed and judgments of the study team. Chemical analysis of spot samples of wastes obtained from industry sources aided in the quantification and substantiation of some of the streams classified as potentially hazardous.

During the course of the study, the following hazardous constituents were found to be in the wastes:

- . Phenols
- . Antimony, zinc and manganese ions
- . Aromatic and chlorinated hydrocarbons
- . Diamines and dithiocarbamate dusts
- . Maleic anhydrides.

The discussion below briefly presents information on why these substances are considered to be hazardous. The next section, 4.3.2, relates the substances identified to specific waste streams generated by this industry.

4.3.1.1 Phenols

Phenols have been assigned (1,2,3) a high hazard rating. That is, death or permanent injury may occur after very short exposure to small quantities. In acute phenol poisoning, the main effect is on the central nervous system; chronic poisoning, following prolonged exposures to low concentrations of the vapor or mists, results in digestive disturbance (vomiting, difficulty in swallowing, extensive salivation, diarrhea, loss of appetite), nervous disorders and skin irritations. Chronic poisoning may terminate fatally in cases with extensive damage to the kidneys or liver. Phenols have been assigned a moderate hazard rating⁽³⁾ for flame, explosion and reaction in soil.

- (1) Dangerous Properties of Industrial Materials (4th Ed.) N. Irving Sax (New York: Van Nostrand Reinhold Company, 1974).
- (2) Clinical Toxicology of Commercial Products (3rd Ed.) Gleason, Gosselin, Hodge and Smith (Baltimore: The Williams & Wilkins Co., 1969).
- (3) A Study of Hazardous Waste Materials, Hazardous Effects and Disposal Methods, Booz Allen Applied Research, Inc., United States Environmental Protection Agency (Contract #68-03-0032) (Cincinnati, Ohio: 1972).

4.3.1.2 Antimony Zinc And Manganese Ions

Antimony compounds have been assigned highly⁽¹⁾ and extremely⁽²⁾ toxic ratings. In humans, complaints referable to the nervous system have been reported. Animals exposed to fumes of antimony oxide have developed such symptoms as pneumonitis, fatty degeneration of the liver, polymorphonuclears and damage to the heart muscles.

Zinc salts have been assigned⁽³⁾ a toxicity rating of very toxic. Toxicity and toxic actions are like those of copper salts. They produce irritation or corrosion of the alimentary tract with pain, emesis, etc. Zinc exhibits its greatest toxicity towards fish and aquatic organisms. In soft water, concentrations of zinc ranging from 0.1 to 1.0 mg/liter have been reported to be lethal. The toxicity of zinc salts is increased at lower concentrations of dissolved oxygen in about the same proportion as for lead, copper and phenols, e.g., the lethal concentration at 60% saturation of dissolved oxygen is only about 0.85 that at 100% saturation.

Manganese salts are regarded⁽²⁾ as being moderately toxic to humans. As with industrial exposure to dust, nervous symptoms predominate. In ground water subject to reducing conditions⁽⁴⁾ manganese can be leached from the soil and occur in high concentrations. Many organisms are capable of concentrating manganese in their bodies to many times above the concentration in sea water.

4.3.1.3 Aromatic And Chlorinated Hydrocarbons

Aromatic hydrocarbons are regarded⁽²⁾ to be very toxic and in many cases quite flammable. These materials are toxic by all portals of entry. Some aromatic hydrocarbons are suspected of being carcinogenic agents. Chlorinated hydrocarbons are under suspicion of being carcinogenic. Chlorinated solvents are liver and kidney poisons and central nervous depressants⁽²⁾.

- (1) Dangerous Properties of Industrial Materials (4th Ed.) N. Irving Sax (New York: Van Nostrand Reinhold Company, 1974).
- (2) Clinical Toxicology of Commercial Products (3rd Ed.) Gleason, Gosselin, Hodge and Smith (Baltimore: The Williams & Wilkins Co., 1969).
- (3) A Study of Hazardous Waste Materials, Hazardous Effects and Disposal Methods, Booz, Allen Applied Research, Inc., United States Environmental Protection Agency (Contract #68-03-0032) (Cincinnati, Ohio: 1972).
- (4) Water Quality Criteria, McKee, Y.E., H.W. Wolf, Eds., Resources Agency of California State Water Quality Control Board.

4.3.1.4 Diamines And Dithiocarbamates

Phenylenediamine, for example, is regarded⁽¹⁾ as being very toxic. Indeed, it is a suspected cause of bladder tumors in "aniline" workers.

Dithiocarbamates are also regarded as being very toxic. Zinc dibutyldithiocarbamate is a recognized⁽²⁾ carcinogen. The diethyl and dimethyl analogues are recognized⁽²⁾ as being carcinogenic, as well.

4.3.1.5 Maleic Anhydrides

Maleic anhydride, when reacted with water, will produce heat. When heated, it will emit toxic fumes. In addition, its acute local and systemic effects are rated high for humans.

4.3.2 Potentially Hazardous Waste Streams

The following discussion presents those waste streams which are potentially hazardous and the rationale behind their classification, case by case.

Foster D. Snell, Inc., analyzed waste samples obtained from industry sources to spot check the assumptions made as to components and concentrations constituting the wastes. The results of the analytical program and the methodology employed in the analysis of wastes are presented in Appendix B.

4.3.2.1 Wastes From Phenolic Production

The wastes from phenolic production present themselves in the form of: solutions containing a large amount of water with variable concentrations (5% to 15%) of the organic materials, specifically phenols and discarded off-grade, partly unreacted products also containing excess phenols. This waste stream has high toxicity because phenol compounds are present.

4.3.2.2 Wastes In Amino Resins

In at least one instance, the disposal of partly unreacted amino resins has been mentioned. This stream is fortuitous in nature, resulting from equipment breakdown or human error. However, its occurrence over a period of time cannot be discounted.

(1) Clinical Toxicology of Commercial Products (3rd Ed) Gleason, Gosselin, Hodge and Smith (Baltimore: The Williams & Wilkins Co., 1969).

(2) Dangerous Properties of Industrial Materials (4th Ed.) N. Irving Sax (New York: Van Nostrand Reinhold Company, 1974).

The toxicity of the streams results from excess unreacted formaldehyde. In addition, an overhead stream of formaldehyde contaminated methanol is produced. This stream is considered hazardous because of the toxicity of formaldehyde combined with the high flammability of the mixture.

4.3.2.3 Antimony And Manganese Catalysts In Polyester

The literature indicates the use of acetates of cadmium, cobalt and manganese in polyester production. In addition, the antimony-containing catalyst has also been mentioned in the industry interviews. A stream of waste catalysts (as distinct from a potential catalyst sludge, which was not mentioned in any interview) originates from the very dust control equipment installed to protect the workers handling this material. The toxicity of this stream results from the chemical species -- antimony, manganese or cadmium.

4.3.2.4 Still Bottoms

Still bottoms are those fractions obtained from rectification columns used to purify or separate solvents. There are two types of still bottoms: aqueous and non-aqueous.

As a rule, the aqueous still bottoms are handled in wastewater treatment facilities where they do not present any particular problem. Sometimes these aqueous still bottoms may contain immiscible oils which are separated at the treatment facilities.

The non-aqueous still bottoms may be potentially hazardous by reason of their flammability. In addition, they may be considered suspect if they contain significant amounts of polycyclic aromatics. For these reasons, it would appear that the still bottoms generated in the manufacture of the products listed below are potentially hazardous:

- . ABS-SAN
- . Polystyrene
- . Polypropylene
- . SBR (solution process)
- . Polybutadiene
- . Neoprene.

4.3.2.5 Waste Solvents In Silicone Resin Production

The production of silicone resin is carried out in only five plants in the United States. The technology is perhaps the most proprietary of those encountered in the whole industry (with the possible exception of spinning).

Improper disclosure of confidential information may result from detailed discussion of this item. Special disposal of these solvents has been reported which, by implication, classifies them as potentially hazardous wastes.

4.3.2.6 Hazardous Wastes In Rayon Production

Recently, production of rayon in the United States has declined considerably. Economic considerations have been always mentioned for the closure of production facilities. Nevertheless, another potential cause of this trend may have been the impossibility of meeting effluent guidelines for wastewater. Thus, the classification of some of the streams from the rayon process as potentially hazardous may be academic. Two areas of potentially hazardous waste include:

- Dusts or spills from the handling of dithiocarbamates and ethylene diamine, which have been mentioned as additives
- Highly metal contaminated wastewater treatment sludges.

Considerable amounts of zinc have been reported in the wastewaters. This, in turn, would be precipitated as zinc oxide in the sludge. Zinc oxide is highly leachable and, thus, the sludges are potentially hazardous. An amount of 25-50 Kg/KKg of product (dry weight) has been reported for rayon production sludges.

4.3.2.7 Hazardous Wastes In Acrylic And Modacrylic Production

In this production, a considerable amount of zinc-bearing wastewater sludges has been reported.

4.4 Waste Quantification For The Years 1974, 1977 And 1983 (Plastic Materials And Synthetics Industry)

In this portion of the report, estimated total and potentially hazardous waste quantities for the industry are presented for the year 1974, and projections are made for 1977 and 1983. The data is based on the results of industry interviews, literature search, the analytical procedures carried out on actual waste samples obtained from industry sources and the INFORUM input/output model.

The required information is presented in a series of tables:

- . Table II-40 -- Estimated 1974 Geographic Distribution Of Wastes For The Major Polymerization Operations
- . Table II-41 -- Estimated 1974 Geographic Distribution Of Wastes For The Spinning Operations
- . Table II-42 -- Total Estimated Wastes For The Years 1974, 1977 And 1983.

The following paragraphs discuss the rationale used in developing these tables.

4.4.1 Total Wastes

Total wastes for the industry in 1974 were developed by multiplying the sum of the waste factors for each of the products manufactured (found in Tables II-37 and II-39) by the production values for these products.

- . Table II-40, provides the total wastes by product for 1974 for polymerization operations.
- . Table II-41, does the same for spinning operations.

The values presented in Tables II-40 and II-41 were added together to obtain the 1974 values presented in Table II-42, which summarizes the wastes for SIC 282 as an aggregate.

TABLE II-40 (1)

ESTIMATED 1974 GEOGRAPHIC DISTRIBUTION OF
WASTES FOR THE MAJOR POLYMERIZATION
OPERATIONS OF THE PLASTIC MATERIALS AND
SYNTHETICS INDUSTRY--SIC 282 (6)
(WET BASIS) (KKg/YEAR)

Notes

(D) = Withheld to avoid disclosing figures for individual companies.

(1) Negligible, less than 10 KKg for entire country

(2) Nylon 6 and Nylon 6, 6

(3) No potentially hazardous wastes

Source: Foster D. Snell, Inc. compilations and analysis of waste streams reported during the industry survey.

Notes:

+ Indicates that waste values for state and regions interchange more than the weight indicated. Absolute volumes could not be repeated due to disclosure problems.

(D) Values not given due to possibility of disclosure

(1) Based on Tables II-

(2) Based on weighted average growth in SIC 2821, 2822, 2823 and 2824 for these years as estimated from INFORM input/output model use.

The basic factors influencing the evaluation of solid waste volume for 1977 and 1983 are:

- . Production volume changes
- . The effect of more stringent requirements of water pollution control.

The waste loads for 1977 are expected to vary only with changes in production output. The effect of the 1977 Water Effluent Guidelines Regulations is not expected to be significant because, as most of the plant personnel interviewed indicated, the technology necessary to meet the 1977 requirements is already in place. Thus, the waste factors developed in this study already account for this technology.

For 1983, the cumulative effect of uncertainties in changes of production volume and water regulations is such that the only feasible approach to making the projections, at present, appears to be to discount elements other than production growth. This situation results because the analysis of non-water impacts of the 1983 Water Effluent Guidelines (as presented in the Development Documents for the relevant industries), does not appear to provide the information necessary to evaluate realistically the changes in waste factors per unit production. The procedure followed for the 1983 projections is, therefore, based on changes in production volume only.

Estimates of production for the years 1977 and 1983 were obtained from the Interindustry Economic Research Project of the University of Maryland (INFORUM) input/output model of the U.S. economy. The model analyzes the economy into 200 industrial sectors generally corresponding with the four-digit 1967 Standard Industrial Classifications. The model, its inputs and assumptions are discussed in Appendix A.

Table II-43 presents production in terms of producer prices (1972 dollars) for the years 1974, 1977 and 1983 for each of the four-digit SICs comprising SIC 282.

TABLE II - 43

PRODUCT SHIPMENTS IN PRODUCER PRICES
FOR THE PLASTIC MATERIALS AND SYNTHETICS
INDUSTRY -- SIC 282

SIC	Industry	Product Shipments in Producer Prices (Millions of 1974 Dollars)			% Change Over 1974
		1974	1977	1983	
2821	Plastic Resins	6,266	8,013	11,454	+83%
2822	Synthetic Rubber	1,345	1,489	1,605	+19%
2823	Cellulosic Manmade Fibers	681	840	933	+37%
2824	Manmade Fibers, Non-Cellulosic	3,454	4,099	5,094	+48%
282	Plastic Materials and Synthetics				+56%(1)

(1) Weighted average growth rate developed from 1974 production volume breakdown of SIC 2821, 2822, 2823 and 2824 as presented in Tables II-12, II-14, II-26 and II-28. For example, the contribution of SIC 2821, 2822, 2823 and 2824 to total SIC production volume for 1974 are 38%, 17%, 2% and 43%, respectively. Thus, SIC 282 weighted average growth rate for 1977 is: $(38\% \text{ of } 28\%) + (17\% \text{ of } 11\%) + (2\% \text{ of } 23\%) + (43\% \text{ of } 19\%) = 21\%$.

Source: INFORUM Input/Output Model, University of Maryland, June, 1975.

A weighted average growth rate for the entire SIC 282 was developed based on 1974 production volume breakdown of SIC 2821, 2822, 2823 and 2824. This growth rate for the years 1977 and 1983 are projected to be:

Table II-44 -- Projected Average Growth Rate Over 1974

	<u>1977</u>	<u>1983</u>
SIC 282	21%	56%

Source: Table II-42

These growth rate factors were multiplied by the estimated 1974 wastes to project the 1977 and 1983 loads.

Total wastes for the years of interest are estimated as follows:

Table II-45 -- Estimated Total Wastes For 1974, 1977 and 1983
(KKg/yr.)

	<u>Wet Basis</u>	<u>Dry Basis</u>
1974	2,751,319	1,504,469
1977	3,329,095	1,820,407
1983	4,294,533	2,348,326

Based on an estimated industry wide total, 1974 production of 30,472 KKKg, total wastes amount to 6% of production volume on a weight basis.

4.4.2 Potentially Hazardous Wastes

Potentially hazardous waste quantities for 1974 by product are presented in Table II-40 and II-41. Table II-42 presents total potentially hazardous wastes for the entire SIC 282 for the years 1974, 1977 and 1983.

The information presented in these tables was arrived at in a manner similar to that used for total wastes, as discussed in Section 4.4.1. The values were developed by taking the starred (*) waste factors (those considered to be potentially hazardous) from Tables II-46 and II-47 for each product and multiplying them by their respective production from Tables II-8, II-11, II-32 and II-34. Tables II-40 and II-41 were then totaled to produce the potentially hazardous waste values in Table II-42 for 1974. The values for 1977 and 1983 were developed using the average weighted growth factors as per Section 4.4.1.

From Table II-42, potentially hazardous wastes for the years of interest are summarized as follows:

Table II-48 -- Estimated Potentially Hazardous Wastes For 1974, 1977 and 1983 (KKg/Yr.)

	<u>Wet Basis</u>	<u>Dry Basis</u>
1974	740,351	157,347
1977	895,824	190,389
1983	1,155,614	245,602

Within SIC 282, the largest contributors to the potentially hazardous land destined wastes are:

- . Polystyrene
- . Phenolics
- . Amino resins
- . Acrylics (spinning processes).

The largest single contributor is phenolics with an estimated 366,000 KKg in 1974 of an aqueous solution of phenol and formaldehyde as the potentially hazardous constituent.

5. TREATMENT AND DISPOSAL TECHNOLOGY FOR POTENTIALLY
HAZARDOUS WASTES IN THE PLASTIC MATERIALS AND SYNTHETICS
INDUSTRY, SIC 282

In the preceding section the potentially hazardous waste streams generated by SIC 282 have been described and quantified. In this section these streams are correlated to the specific disposal methods used and the adequacy of these methods assessed in the light of three levels of technology defined below.

- . Level I -- Technology Currently Employed
By Typical Facilities. This level represents the broad average treatment and disposal practice.
- . Level II -- Best Technology Currently Employed. This level represents the best practice from an environmental and health standpoint, currently in use in at least one location. Installations must be commercial scale. Pilot and bench scale installations are not suitable.
- . Level III -- Technology Necessary To Provide
Adequate Health And Environmental Protection. Level III technology may be more or less sophisticated or may be identical with Level I or II technology. At this level, identified technology may include pilot or bench scale processes providing the exact stage of development is identified.

The disposal methods presently encountered in this industry are:

- . Incineration
- . Landfill
- . Lagooning
- . Storage

It should be noted that contract disposal ultimately results in the use of one of the above methods.

The discussion of the treatment and disposal methods applicable to the potentially hazardous waste streams in SIC 282 differs somewhat from that presented in the following chapter for SIC 30 industry. The reasons are considerable differences:

- . in production technologies
- . in nature of waste streams
- . in disposal technology
- . in degree of development of potential technologies.

In the subsequent sections the broad categories of applicable disposal technologies are presented, followed by a detailed discussion of treatment and disposal technology by types of hazardous waste.

5.1 Treatment And Disposal In SIC 282

The following paragraphs discuss treatment and disposal technologies applicable to the Plastic Materials and Synthetics Industry. In some instances restrictions on the permissibility of alternative disposal methods may shift the disposal of certain streams in the direction of recovery. For instance, the additional expense of meeting adequate standards in disposal method X, currently practiced, added to the presently insufficient value of the recovered product, may make recovery economically attractive.

In many instances, however, indefinite recovery and reuse may not be feasible due to accumulation of undesirable impurities. In this case, a portion of the wastes is disposed of through other methods. This appears to be the case for the disposal of zinc oxides to landfill at certain plants of SIC 282.

5.1.2. Controlled Incineration

This method is universally practiced in the SIC 282 industries. Indeed, the fact that a waste is incinerated may be taken as prima-facie evidence of the undesirability of disposing of it by other methods. However, it is not always the case. For example, incineration may be more economical than landfilling because of considerations of volume, transportation costs or value of the waste as a fuel. An extreme case is that of the coumarone-indene industry in which some waste streams are indistinguishable from #2 fuel oil. At present, state regulations are such that monitoring and control are the rule on all incineration equipment. Installations still lacking in these features are scheduled to be equipped or replaced to meet the standards. Incineration can be performed on-site or contracted out. The only reason for contracting out is economics and thus contracting out does not represent a technological alternative.

5.1.3. Open Dumping

The majority of industry firms contacted have become increasingly aware of their responsibility for the proper treatment and disposal of their wastes. They have related, during the course of the interviews, that they are taking an active role in investigating what is occurring at their own sites as well as those of private contractors.

5.1.4. Burial Operations And Landfills

These represent the other major disposal technology used in SIC 282 for those wastes which are classified as potentially hazardous and which are not incinerated. These wastes are essentially wastewater treatment sludges contaminated by metal ions. When inadequate landfill sites are still in use, measures are universally being taken to improve the situation by resorting to secure landfill. Since this technology is more universally used for SIC 30 and to avoid repetition, the detailed discussion of these operations is in Chapter III, Section 7.3.

5.1.5. Ponding And Lagooning

This represents a technology widely used in the production sites of SIC 282, particularly on the Gulf Coast. However, no significant amount of potentially hazardous wastes originating in SIC 282 operations appear to be disposed of by this technique.

This technique provides a simple and economic approach to on-site potentially hazardous waste disposal, where applicable. However, there are some significant drawbacks.

- . The pond must provide protection from both surface and groundwater contamination. In almost all areas, this requires a liner. Liners include clay, plastic, concrete, and epoxy, all of which are relatively expensive.
- . Except in very dry climates, ponds without discharge will overflow from rainfall accumulation.
- . Ponds are prone to be "flushed out" with massive rainfall. It is difficult and expensive to provide flood protection.

The type of production carried out at most of the sites is such that it is impossible to evaluate precisely the contribution to the utilization of these facilities by processes involving SIC 282 products. At most, 5% to 10% of the streams collected in such facilities come directly from SIC 282 operations, and in no case have these been considered potentially hazardous.

5.2 Treatment And Disposal In SIC 282 By Hazardous Waste Type

It is evident from the discussion in the previous sections that the segmentation of SIC 282 into the Department of Commerce segments does not provide a sound framework for the technical discussions associated with products and processes. In particular, the distinction between SIC 2821, Plastics, and SIC 2822, Synthetic Rubber, is inapplicable since the same name processes (e.g., Ziegler or Phillips) are used for some products in both segments.

5.2.1 Treatment And Disposal Of Potentially Hazardous Wastes Generated In Phenolics Production

The phenolic resins constitute the one group in which a substantial potentially hazardous waste problem exists for the following reasons:

- . Substantial production (610 KKKg/yr)
- . Large volume of potentially hazardous wastes (50% by weight)
- . Inadequate present long range disposal methods.

For treatment and disposal the potentially hazardous wastes generated in the manufacture of phenolic resins are separated into two streams:

- . A liquid stream of low viscosity, containing organics including phenols and/or formaldehyde easily pumpable with varying degrees of turbidity
- . A solid/semi-solid of varying consistency which contains oligomers and excess phenol and which is difficult, if not impossible, to pump by conventional means.

At present the practice is to incinerate the liquid stream and to store the solid/semi-solid stream in ponds or lagoons until a satisfactory disposal method has been developed.

A problem associated with the incineration of the liquid stream is that it does not contain enough organic material to sustain its own combustion. At one of the sites visited, a backlog of waste solvents of various origins (mostly outside the scope of SIC 282 operations)

has permitted the incineration of this stream without use of purchased fuel for the past several years. However, this practice is not generally feasible. It appears that the stream to be incinerated does not bring elements requiring further treatment of the combustion gases. At the other plants, this material is generally stored on-site in drums.

Obviously, even though the precautions to prevent dispersion into the environment of the solid/semi-solid stream are presently satisfactory, storage is not an environmentally adequate solution in the long run. The viscosity of this material prevents its disposal by incineration, at least in the incinerator configurations commercially available today. Disposal methods are reportedly under investigation. But due to their specialized nature and the disproportionate costs of development, these methods are kept strictly proprietary.

5.2.2. Potentially Hazardous Waste Constituted By Partly Unreacted Amino Resins

Equipment upsets or human error are responsible for the wastes destined for land disposal and the need to dispose of relatively small amounts of partly unreacted mixtures of urea or melamine and formaldehyde. The material is drawn off from the reactor, drummed in sealed drums and adequately incinerated under contract by a professional waste treatment firm. This, provided that the treatment firm is aware of the potential hazard to the immediate personnel, appears to constitute an environmentally adequate disposal method. If local incineration facilities exist, there is no reason not to dispose of this material via that route.

5.2.3. Potentially Hazardous Waste Created By The Handling Of Catalyst In Polyester Production

A waste stream consisting of a mixture of manganese salts and antimony compounds has been reported by polyester manufacturers. Proprietary considerations have prevented further inquiry into the extent of this stream. Literature confirms the use of salts of manganese, cobalt and cadmium as catalysts in polyester production. At present the material is stored in drums until development of a more suitable disposal method occurs. However, technology for adequate disposal would appear to be disposal in a secured landfill.

5.2.7 Potentially Hazardous Waste Solvents In Silicone Production

The industry structure is such that, to preserve confidentiality, little can be said about this stream except that it is disposed of by incineration. Since the operations investigated are carried out in states with strong antipollution regulations, it is assumed that incineration is carried out in an environmentally adequate controlled manner.

5.3. Treatment And Disposal Technology Levels As Applied To Potentially Hazardous Wastes Produced By The Plastic Materials And Synthetics Industry, SIC 282

The levels of treatment and disposal technology have been characterized in the opening paragraph of Section 5. The following factors have been employed in evaluating the technologies used or to be developed by the industry for the treatment and disposal of potentially hazardous wastes.

- . Factor I -- Physical And Chemical Properties Of The Waste. This gives a brief description of the form of this waste and identifies the main constituents
- . Factor II -- Amount Of Waste (Kg/KKKg Of Product). This factor gives an average quantity or range of the magnitude of the total potentially hazardous waste streams treated based upon a waste factor relating the quantity of waste (kilograms) to the quantity of production.
- . Factor III -- Factors Affecting Degree of Hazard From The Waste. This gives a brief description of the possible interaction of the surrounding environment with the waste.
- . Factor IV -- Adequacy Of Technology. A description of the technology with respect to environmental considerations and load regulations in terms of present and future conditions.
- . Factor V -- Non-Land Environmental Impact. This describes the possible impact of the technology on non-land environmental factors such as water or air quality.
- . Factor VI -- Problem Areas Or Comments. A brief description of problem areas encountered with the technology or important comments.
- . Factor VII -- Compatibility With Existing Facilities. This evaluation factor describes whether the technology can be used by existing plants or waste disposal contractors.

- . Factor VIII -- Monitoring And Surveillance Techniques. This describes the type and frequency of monitoring necessary for the technology.
- . Factor IX -- Installation Time For New Facility. This factor provides information on whether or not the treatment and disposal technology has been installed or how long it will take to get it on-stream.
- . Factor X -- Energy Requirements. This factor describes the qualitative amount of energy required for the technology.

With the exception of two streams, for which no adequate technology has yet been developed, the treatment and disposal practices of the SIC 282 consist of:

- . Secured landfill
- . Incineration⁽¹⁾
- . Recovery.

The treatment and disposal technologies of the potentially hazardous waste streams discussed in Section 5.2 are applied to the three treatment and disposal technologies in a series of tables.

- . Table II-49, Liquid Phenolic Wastes
- . Table II-50, Solid/Semi-solid Phenolic Wastes
- . Table II-51, Off-Grade Product From Amino Resin Production
- . Table II-52, Waste Catalyst Stream From Polyester Production
- . Table II-53, Still Bottoms (Aromatic, Aliphatic, Chlorinated, Etc.) From All SIC 282 Processes Producing Such Waste Streams
- . Table II-54, Zinc Oxide Sludges From Wastewater Treatment In Cellulosic And Acrylic Fiber Production

(1) Previous studies in this group identified two levels of incineration, so-called uncontrolled and controlled. Air pollution abatement regulations have been instituted in most states, so that incineration as practiced in 1975 is controlled.

TABLE II-49

TREATMENT AND DISPOSAL TECHNOLOGIES FOR
LIQUID PHENOLIC WASTES -- SIC 2821

Factor	Level I, Prevalent Technology	Level II, Best Available Technology	Level III, Adequate Health And Environmental Protection
Physical and Chemical Properties of Residual Wastes	Water solutions of various organic species, including phenols and/or formaldehyde	Same as Level I	
Amount of Residual Wastes (Kg/KKkg Product)	500	Same as Level I	
Factors Affecting Hazardousness	Phenols and formaldehyde are toxic to human, animal and plant life	Same as Level I	
Treatment/Disposal Technology	Drum storage	Controlled Incinerator	
Estimate of Number or Percent of Plants Now Using Technology	50%	50%	Same as Level II
Adequacy of Technology	Inadequate	Adequate if air pollution control is practical	
Non-Land Environmental Impact	None, if drums remain sealed	Same as Level I	
Problems and Comments	Potential for drums to corrode and spill contents	Necessity to "burn" large amounts of water, excessive costs and fuel consumption	
Compatibility with Existing Facilities	Compatible	Same as Level I	
Monitoring and Surveillance Techniques	Periodic inspection of drums to insure they are not leaking	Air monitoring	
Installation Time for New Facility	N.A.	1 Year	
Energy Requirements	None	600 K Cal/Kg(1,100 BUT/lb.)

TABLE II-52

TREATMENT AND DISPOSAL TECHNOLOGIES FOR
OFF-GRADE PRODUCT IN AMINO RESIN PRODUCTION
-- SIC 2821

Factor	Level I, Prevalent Technology		Level II, Best Available Technology		Level III, Adequate Health And Environmental Protection	
	Semi-solid to solid material containing excess formaldehyde		Same as Level I		Same as Level I	
Amount of Residual Wastes (Kg/KKg Product)	10		Same as Level I		Same as Level I	
Factors Affecting Hazardousness	Formaldehyde fumes		Same as Level I		Same as Level I	
Treatment/Disposal Technology	Drumming at site followed by contract incineration by controlled equipment		See footnote (1)		See footnote (1)	
Estimate of Number or Percent of Plants Now Using Technology	100%					
Adequacy of Technology	Adequate					
Non-Land Environmental Impact	None					
Problems and Comments	See footnote (1)					
Compatibility with Existing Facilities	See footnote (1)					
Monitoring and Surveillance Techniques	As required by local ordinances					
Installation Time for New Facility	N.A.					
Energy Requirements	Negligible					

(1) Basically, all such streams can be incinerated. Disposal by contract incineration is subject to the same conditions of volume considerations. Conceivably some production sites may have local incineration, usually by reason of other production. Such situation cannot be construed as Level II, because contract incineration is, by definition, environmentally adequate.

N.A. = Not Applicable

TABLE II-54

TREATMENT AND DISPOSAL TECHNOLOGIES FOR ZINC
OXIDE SLUDGES FROM WASTEWATER TREATMENT
IN CELLULOSIC AND ACRYLIC FIBER PRODUCTION

-- SIC 2824

Factor	Level I, Prevalent Technology	Level II, Best Available Technology	Level III, Adequate Health And Environmental Protection
Physical and Chemical Properties of Residual Wastes	Watery solids and semi-solids containing large amounts of zinc oxide	Same as Level I	<div style="text-align: center;"> <div>←</div> <div>→</div> </div> Same as Level II
Amount of Residual Wastes (Kg/KKkg Product)	Variable depending on operating conditions	Same as Level I	
Factors Affecting Hazardousness	Potential leaching of zinc ion into ground and surface	Same as Level I	
Treatment/Disposal Technology	Secured landfill	Recovery (2)	
Estimate of Number or Percent of Plants Now Using Technology	Variable, depends on economics	Variable depends on economics	
Adequacy of Technology	Adequate if landfill is secured	Adequate	
Non-Land Environmental Impact	Potential dispersion of zinc ion into ground and surface water	None, if appropriate control equipment is installed on recovery facilities.	
Problems and Comments	The industry is acutely aware of leaching problem. Practically all the sludge is being disposed off properly.	Preferable technology from environmental standpoint both directly and indirectly.	
Compatibility with Existing Facilities	Compatible	Installation of on-site recovery facilities may be impossible due to space limitations.	
Monitoring and Surveillance Techniques	Monitoring of ion concentration at landfill sites	Appropriate control of streams from the recovery process	
Installation Time for New Facility	Variable depending on locations; Up to 1 to 2 years	1 Year	
Energy Requirements	Minimal	Minimal	

(1) The selection of disposal technology is a matter of economics. It varies not only from plant to plant but in time at the same point in function of the variations of market prices for zinc and zinc salts.

(2) Recovery takes two forms, on-site and off-site. From technology standpoint the two course are equivalent.

Source: Foster D. Snell, Inc., analysis of company interviews.

6. COST ANALYSIS FOR THE TREATMENT AND DISPOSAL OF
POTENTIALLY HAZARDOUS WASTES IN THE PLASTIC MATERIALS
AND SYNTHETICS INDUSTRY, SIC 282

The cost analysis is presented illustratively. As explained several times in this report, the existence of a well-defined and self-contained production facility for most of the products of this industry is the exception rather than the rule. At most locations facilities are shared with those required to handle the wastes of other products. These "co-products" may belong to the SIC 282 or in entirely different classifications.

A case in point is the generally practiced method of incineration of the organic wastes, particularly liquids. Seldom does the magnitude of streams created by the production of a given resin (e.g., polypropylene) at one site justify the installation and operation of the appropriate treatment and disposal equipment.

Thus, the streams, whether solid or liquid, potentially hazardous or non-hazardous in the sense of this study, are handled as a part, most often small, of the general treatment and disposal system of the production site.

For example one particularly cooperative interviewee provided incineration cost figures calculated at several dollars per pound incinerated. Further inquiry revealed that the reported costs were those of the total incineration facility at the site. The particular streams of interest constituted only a minute fraction of the load of the facility. The same observation applies to wastewater treatment facilities and, therefore, to the disposal of sludge generated.

The estimates presented were prepared on an engineering basis, using accepted engineering format. No attempt was made to prepare estimates which would reflect impact on the financial statements of individual companies. Inclusion of tax considerations, product pricing, and other such factors would involve practices unique to each company and should be recognized as beyond the scope of this report.

Wherever possible, the figures have been cross checked with actual experience in the field as reported by the firms interviewed. However, it must be stated again that this analysis remains purely illustrative.

Bearing in mind the above discussion, evaluation of the costs have been made using the factors outlined below. The section following presents individual case studies for the costs of treatment and disposal of potentially hazardous wastes generated by this industry.

6.1 Cost Elements And Treatment Of Costs

For the purposes of this study, two kinds of costs are presented:

- . Investment costs
- . Annual costs.

The development and treatment of these costs are presented in the following paragraphs, supplemented where necessary by further information detailed in each of the individual cases beginning in Section 6.2.

6.1.1 Investment Costs

These typically represent "front end" costs incurred only once during the acquisition of the required land, buildings and equipment.

The importance of the landfill operations (land intensive) is reflected by the subcategorization of the investment costs into "land" and "other." A nominal land cost of \$12,500 per 10,000 m² (\$5,000 per acre) is used throughout, based on the results of field contacts.

6.1.2 Annual Costs

The two basic groups of annual cost are: first, an annualized cost of investment as defined above and, in this study, called "capital;" and second, other costs. The usual practice is to subdivide these other costs in terms of materials, utilities, labor, maintenance, supplies, insurance, etc.

For the purpose of this study, a different characterization is used:

- . Capital
- . Operating
- . Contractor
- . Energy and power.

This reflects the different nature of the operations involved and the particular interest of the EPA. The composition of these cost elements is indicated below.

6.1.2.1 Capital Cost (Annual)

This is a conversion of the investment cost to an annual sum by application of the conventional Capital Recovery Factor as given in standard accounting manuals. Unless otherwise indicated, the factor used here is 0.163, corresponding to an interest of 10% for a recovery period of 10 years. Implicit is the assumption that the value of the investment is zero at the end of the period. Although this may be valid for specialized equipment (such as incinerators), it does not usually correspond to agreed practices for land and buildings. However, this assumption appears legitimate if, in particular, the land area devoted to landfill is initially calculated for a 10-year capacity. In most instances, the value of the land thus utilized is indeed nil at the end of the fill. Rehabilitation costs of landfill sites to alternative use are estimated to be well in excess of the initial land value in the majority of cases, especially for sites where potentially hazardous wastes have been placed.

6.1.2.2 Operating Costs

In this study, this includes all the variable costs (materials, labor, supplies, maintenance, etc.), except the cost of fuel or electricity.

Labor costs are taken as \$15,000 per year for general non-supervisory personnel and \$25,000 per year for supervisory personnel. Part-time use is prorated.

6.1.2.3 Hazardous Wastes Disposal Contractor Costs

This cost element is usually employed in lieu of operating and capital cost or as a supplement to it. It is an important element in the next chapter, Rubber Products Industry SIC 30, and its magnitude there is discussed separately. The cost used here reflects actual experience.

6.1.2.4 Energy And Power

Fuel costs are taken as \$10 per barrel for fuel oil and \$0.15 per liter (\$0.60 per gallon) for gasoline. Natural gas is estimated at \$0.09 per cubic meter (\$1.25 per million BTUs).

6.2 Case Study Of Potentially Hazardous Waste Treatment And Disposal Costs

In this section, costs for the treatment and disposal of typical potentially hazardous wastes are estimated for individual products and waste streams based on the technologies defined in Section 5. The following list details the products or categories for which the costs were developed and the tables summarize the estimates for each of the products.

- . Liquid Wastes From Phenolic Resin Production--
Table II-55
- . Solid And Semi-Solid Wastes From Phenolic Resin
Production -- Table II-57
- . Still bottoms generated from the production of
 - Styrene Butadiene Rubber -- Table II-58
 - Polystyrene -- Table II-59
 - Acrylonitrile Butadiene Styrene -- Table II-60
 - Polypropylene -- Table II-61
 - Polybutadiene -- Table II-62
- . Zinc sludges from the production of
 - Rayon Fibers -- Table II-66
 - Acrylic Fibers -- Table II-69.

Detailed costs are not provided for the treatment and disposal of solid and liquid wastes from amino resin production because these costs are small and production techniques are so varied that even illustrative examples would not be valid.

For each of the products presented above, wherever applicable, the three levels of technology or variations are also taken into consideration.

6.2.1 Costs Of Treatment Disposal Of Liquid Wastes In Phenolics Production

The present practice is to incinerate the water waste stream containing 10% to 15% organics, with additional fuel required to support combustion. This practice is adequate from the standpoint of direct environmental impact. However, it requires a considerable amount of fuel to convert the water into steam during or prior to the combustion process.

The costs elements are:

- . Incineration: The cost of an incinerator of the required capacity is estimated at about \$1,000,000 installed, according to industry contacts.
- . Annualized capital ($\$1,000,000 \times 0.163$) = \$163,000
- . Labor (4 man-years) = \$60,000.
- . Fuel: The fuel requirements vary from zero, if the stream contains more than 12% organics, to about 2,400 barrels, if it contains 5% organics. For this latter case a cost of \$24,000 per year for fuel may be encountered.

Costs are summarized in Table II-55.

6.2.2 Costs Of Treatment And Disposal Of Solid And Semi-Solid Waste Streams In Phenolics Production

- . Level I. The present practice is to store the material in drums or in secure containment until development of suitable technology.
- . Level II. Incineration, made possible by the production (at the same site) of large amounts of other materials with which the stream is mixed.
- . Level III. This is proprietary technology, said to be under development. None presently available.

Level I	Incineration with additional fuel		
Level II	Same as Level I		
Level III	Same as Level I		

Source: Foster D. Snell, Inc., analysis of interviews and literature data.

The cost elements are:

- Drum storage: Each drum contains about 200Kg (450 lbs.) of material. Thus, 5 drums are required per ton of product; that is, 4,500 drums per year. The costs are estimated at \$3.25 per drum, covering the cost of the drum, the handling and the value of the storage space. Thus, the cost is estimated at \$16.25 per ton or about \$15,000 per year.
- Incineration: In this example, the stream to be incinerated represents 5% of the capacity of the incinerating system. Therefore, a capacity of 18,000 Kkg of incineration per year is required. The costs are allocated back on the basis of 5% utilization of the capacity. The cost of the required incinerator is estimated at a total of \$4,000 000. It requires four-man operation and one supervisor. Total labor costs: \$85,000. Auxiliary fuel required is estimated at 5 barrels per day. Maintenance (at 1% of installation) costs \$40,000 per year. The fuel costs would thus be about \$12,000 per year. The share borne by the incineration of the subject stream is given in the following table.

Table II-56 -- Incineration Costs In Phenolics Production

Investment (\$4,000,000 x 0.05)	\$200,000
Cost of capital (\$200,000 x 0.16)	32,000
Operating cost (\$125,000 x 0.05)	6,250
Fuel cost (\$12,000 x 0.05)	<u>600</u>
Total	\$238,850

- Proprietary Technology Development: The technology for this level is reported under development. Costs and other data are highly proprietary. It should, however, present a substantial economic advantage over present practice.

Costs are summarized in Table II-57.

6.2.3 Costs Of Treatment And Disposal Of Still Bottoms In A SBR Plant

All that is required for the environmentally adequate disposal of this waste is the existence of a large enough pool of mixed material to be burned (incinerated) so that the flame adjustment does not have to be changed frequently.

Source: Foster D. Snell, Inc., analysis of interviews and literature data.

The cost elements are:

- . The average plant may have to burn about 5.6 Kg of still bottoms per 1,000 Kg of product. With a production of 60.4 KKKg per year, this represents about 200,000 Kg of product per day or 1,000-1,500 Kg of still bottoms. This is 1,500 liters per day (400 gallons per day) or almost 8 drums.
- . The required incinerator is comparatively very small. The cost is about \$50,000 installed. It requires less than 1/4 man-day for operations. No significant auxiliary fuel is required and less than \$1,000 per year of maintenance is necessary.

It is to be noted that in real life this would not necessarily be the case. The stream could in fact be disposed of:

- As auxiliary boiler fuel
- As a small part of a much larger feed stream to a centralized facility.

The costs presented here are illustrative and are summarized in Table II-58.

6.2.4 Costs Of Treatment And Disposal Of Still Bottoms In A Polystyrene Plant

The still bottom produced in this operation is substantially similar to that for the SBR plant previously described. The production of still bottoms is about 10 Kg/ KKKg of product. The production is about 56 KKKg per year and about 560 KKKg of still bottoms are produced. This requires an incinerator of about the same capacity as for the previous plant. However, it is assumed that it will be operated about twice as long. To account for this difference (two shifts/5 days per week instead of one shift), the labor requirements are estimated at 1/2 man-year and the maintenance costs increased to \$1,500 per year.

The costs are summarized in Table II-59.

6.2.5 Costs Of Treatment And Disposal Of Still Bottoms In ABS-SAN Plant

The equipment requirements and costs are the same as for the previously described plant. The typical plant produces 130 KKKg of resin per year and disposes of 650 KKKg of still bottoms per year. The equipment, operating and maintenance costs should be about the same as for the polystyrene plants. The unit costs reflect the small difference in actual production volume and quantity of wastes generated.

The costs are summarized in Table II-60.

6.2.6 Cost Of Treatment And Disposal Of Still Bottoms In A Polypropylene Plant

Here again the costs presented are illustrative. At an integrated production site, for instance, it was found that the incinerator used for the liquid organic wastes had a capacity of 6,500 KKg per year; had cost \$3,200,000 (1974 dollars); and had an operating cost (excluding capital cost of \$160,000 per year. Thus, in the terms of this study, it had an annual cost of \$672,000 per year. With the average polypropylene installation used for this study, 933 KKg of still bottoms would be produced by the polypropylene unit. The prorated costs would then be about \$96,000 for this particular site. It is to be noted that, of these costs, \$62,000 are costs of capital, as computed for this study. These figures differ considerably from those which were allocated to the polypropylene stream at that location.

Should an installation be provided for the estimated still bottom stream of 933 KKg per year, it is estimated that a comparatively small burner--3,000 Kg per day or, say, \$3,000 per day (150 gallons)--could be used. A unit of this type would probably cost about \$75,000. Given 1/2 man-year of operation and about \$1,500 per year of maintenance, the operating cost would be about \$9,000 per year. The cost of capital would be \$12,000, and the total annualized costs would be \$21,000.

These costs are summarized in Table II-61.

6.2.7 Cost Of Treatment And Disposal Of Still Bottoms In A Polybutadiene Plant

Again, the polybutadiene production facility would in reality be part of a large production complex of which it would constitute only one unit; it would share feed-stock and services with the other utilities.

However, in this case, the extreme smallness of the still bottom stream, estimated at only 4.8 KKg per year, would permit another solution.

Such a small stream cannot justify the installation of an incinerator in the hypothetical case of a single standing plant. In this case the practice would be to contract the incineration. In another study, currently being performed for the EPA, Foster D. Snell has obtained data indicating an average national cost of \$0.12-0.15 per gallon for contract incineration of combustible liquid waste. This averages to about \$50 per KKg of waste and is the basis of the costs presented in Table II-62.

6.2.8 Costs Of Treatment And Disposal Of Sludge Containing Zinc In A Rayon Plant

In the United States six plants manufacture rayon. The typical plant produces 60 KKKg (132,000,000 lbs.) per year. Such a plant has to dispose of 12,000 KKKg (26,400,000 lbs.) of zinc containing sludge per year. This represents about 10,000 m³ (13,000 cu. yds.) of sludge per year.

This sludge contains about 10% zinc hydroxide; that is, 1,200 KKKg (2,640,000 lbs.)

The cost elements are:

Level I. This technology consists of disposal to secured landfill. The operating costs for a secured landfill at a typical production site amount to

- Labor: \$1,500/1000 m³
- Fuel: \$500/100 m³

The investment for a secured landfill, exclusive of land, is estimated at \$125,000 per 10,000 m² (\$50,000/acre). This includes excavation, drainage, test wells and a prorated volume as utilized for the sludge.

The yearly land requirement is 2,000 m² (0.5 acre). The landfill site is assumed to be prepared for a 10-year capacity. Thus, a land area of 20,000 m² (5 acres) is required. The land value is estimated at \$12,500 per 10,000 m² (\$5,000/acre). The cost of disposal estimated by this method is given in the following table.

Table II-63 -- Level I Disposal Costs In Rayon Production

Investment costs

Land (20,000 m ² @ \$1.25/m ²)	\$ 25,000
Other (20,000 m ² @ \$12.5/m ²)	<u>250,000</u>
Total	<u>\$275,000</u>

Annual costs

Capital costs (\$275,000 x 0.16)	\$ 44,000
Operating costs (\$2,000 @ \$1.50)	3,000
Fuel costs (\$2,000 @ \$0.50)	<u>1,000</u>
Total	<u>\$ 48,000</u>

Level II. This involves the installation of a zinc recovery unit.

The cost of such a unit treating 20,000 m³ per year is reported to be \$2,750,000.

Using the conventional engineering scaling factor, 0.6 power of the size, the cost of a recovery plant treating 10,000 m³ of sludge per year is estimated at \$1,800,000.

The operating costs of the 20,000 m³ per year unit are reported to be \$125,000 per year. These represent mostly labor costs. Thus, the cost of operating the smaller plant is estimated at \$100,000. The energy costs are considered to be almost \$2,000 per year.

The costs of operating the recovery unit are summarized in the following table.

Table II-64 -- Level II Operating Costs For Zinc Recovery Unit In Rayon Production

Investment costs	Negligible
Other	<u>\$1,800,000</u>
Total	<u>\$1,800,000</u>
Annual costs	
Capital costs (\$1,800,000 x 0.16)	\$ 288,000
Operating costs	100,000
Fuel	<u>2,000</u>
Total	<u>\$ 390,000</u>

However, the plant recovers the zinc chloride. The net value of the material thus recovered (after deduction of the cost of the required hydrochloric acid and adjustment for 90% yield of recovery) is estimated at \$1,100,000.

The process is reported to reduce the volume of sludge to 1/3 the original. Therefore, the disposal of 3,300 m³ per year has to be taken into account.

Based on the same assumptions and estimates as used with regard to Level I disposal, the cost of disposing of this sludge is estimated in the following table.

Table II-65 -- Level II Disposal Costs In Rayon Production

Investment costs

Land (7,000 m ² @ \$1.25/m ²)	\$ 9,000
Other (7,000 m ² @ \$12.5/m ²)	<u>88,000</u>
Total	<u>\$ 97,000</u>

Annual costs

Capital costs (1,897,000 x 0.16)	\$303,000
Operating costs	101,050
Fuel	<u>2,350</u>
Total	<u>\$406,400</u>

The operation thus appears to achieve a net operating profit of about \$700,000 per year.

Level III. Since both Level I and Level II technologies are considered environmentally adequate, they each represent Level III technologies. Therefore, Level III-technology 1 is estimated to be the same as Level I and Level III-technology 2 is the same as Level II.

All the cost data are summarized in Table II-66.

6.2.9 Costs Of Treatment And Disposal Of Zinc Containing Sludge In Acrylic And Modacrylic Plants

The typical acrylic/modacrylic processing plant has a production level of 130 KKKg (290,000,000 lbs.) per year. It produces about 26,000 KKg of zinc containing sludges. This represents about 24,000 m³ (31,000 cu. yds.) per year.

This sludge contains about 5% of zinc hydroxide. This would represent about 1,300 KKg per year.

The disposal of this sludge is identical to disposal methods practiced in the rayon plant, as described in the preceeding sub-sections.

TABLE II-66

RAYON: TYPICAL PLANT DISPOSAL COSTS FOR
ZINC CONTAMINATED SLUDGE -- SIC 2823

Source: Foster D. Snell, Inc., analysis of interviews and literature data.

Using the same cost parameters, the following costs can thus be estimated:

Table II-67 -- Level I Disposal Costs In Acrylic And Modacrylic Production

Investment costs

Land	\$ 60,000
Other	<u>600,000</u>
Total	<u>\$660,000</u>

Annual costs

Capital	\$105,600
Labor	7,200
Fuel	<u>2,400</u>
Total	<u>\$115,200</u>

Level II. Recovery

It is assumed that the plant reported is designed to handle 20,000 m³ per year of 10% sludge and is adequate to handle 24,000 m³ per year of 5% sludge.

It is further assumed that the same sludge volume reduction is encountered.

The value of the recovered zinc chloride is estimated at \$1,220,000 per year. Therefore, the recovery costs presented in the following table result.

Table II-68 -- Level II Total Zinc Recovery Costs In Acrylic And Modacrylic Production

Investment costs

Land	\$ 20,000
Other	<u>2,950,000</u>
Total	<u>\$2,970,000</u>

Annual costs

Capital costs	\$ 475,000
Operating costs	125,000
Energy costs	<u>3,000</u>
Total	<u>\$ 603,000</u>

There is a net operating profit of \$617,000.

The cost figures are summarized in Table II-69.

6.3 Costs Of Disposal Of Potentially Hazardous Wastes Affecting The Various Segments Of The Plastic Materials And Synthetics Industry, SIC 282

The costs data developed for the various individual products in the previous sections are summarized for the relevant segments of the Plastic Materials and Synthetics Industry and presented in Table II-70.

The costs are in turn expressed as a percentage of the value of the products shipped by the segments of the industry in Table II-71.

However, it must be borne in mind that these figures, for all their precision, are illustrative. They would be substantially affected by shifts in the relative importance of the various products manufactured in each segment of the industry.

Table II-72 presents a synopsis of the findings concerning the potentially hazardous waste streams, their nature, the amounts generated annually, the treatment and disposal technologies and the associated costs on a product-by-product basis.
